Consider:

Thousands of

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

WELLCOVORIN® TABLETS

(leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.[1]

[1]Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

86WCV1R

WELLCOVORIN® TABLETS
(leucovorin calcium)
Leucovorin in convenient 5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

You can help us raise the colorectal cancer cure rate.

"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:
- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces cancer alone.

AMERICAN CANCER SOCIETY®

BLOOD

The Journal of The American Society of Hematology

Blood: The Journal of The American Society of Hematology (ISSN 0006-4971) is published monthly, in two volumes per year, by Grune & Stratton, Inc., 6277 Sea Harbor Dr, Orlando, FL 32821. Second class postage paid at Duluth, MN, and at additional mailing offices.

POSTMASTER: Send change of address to *Blood*, c/o Grune & Stratton, Inc., PO Box 6280, Duluth, MN 55806.

Editorial correspondence should be addressed to:
John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

Correspondence regarding subscriptions or change of address should be addressed to Grune & Stratton, Inc., PO Box 6280, Duluth, MN 55806.

Customer Service: 1-800-654-2452.

Change of address notices, including both the old and new addresses of the subscriber, should be sent to the Publisher at least one month in advance.

Other correspondence (copyediting, production) should be addressed to:

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

Information for Contributors .... xxxiii, xxxiv

Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

(Continued on following page)

(Contents continued)

All manuscripts submitted for consideration for publication in BLOOD should be sent to: John W. Adamson, MD, Editor, BLOOD, University District Building—Room 410, 1107 NE 45th St, Seattle, WA 98105. Telephone: (206) 545-8080.

Please note that a processing fee of $50.00 must accompany each manuscript submitted for publication in BLOOD.

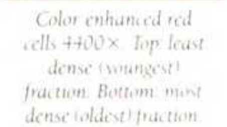
The American Society of Hematology certifies that the continuing medical education offering provided by *BLOOD, The Journal of The American Society of Hematology*, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

NOW YOU CAN
SEPARATE THE BEST FROM THE REST

...WITH THE CUTTER
NEOCEL™ SYSTEM FOR YOUNG RED CELLS.

Now, young red cells can be routinely used to improve the management of chronically transfused patients by decreasing the transfusion requirement and the rate of iron loading... or whenever the best red cell product is indicated. Because now there's a commercially available blood bag system for efficient, reliable separation of red cells by age.

A BETTER RED CELL PRODUCT
The Neocel System delivers a product rich in neocytes (young red cells) with a 31% extension in mean half-life over normal packed red cells.



Color enhanced red cells 4400×. Top: least dense (youngest) fraction. Bottom: most dense (oldest) fraction.

SIMPLE, FAST PROCEDURE
Neocel provides a simple method of separation using a standard centrifuge, significantly reducing cost and technical difficulty compared to present methods.

Provide a better red cell product, with the Neocel System for Young Red Cells... another Component Enhancement Product, only from Cutter.

For more information, contact your Cutter Biological Representative or call our Professional Services Department at (800) 227-1762.

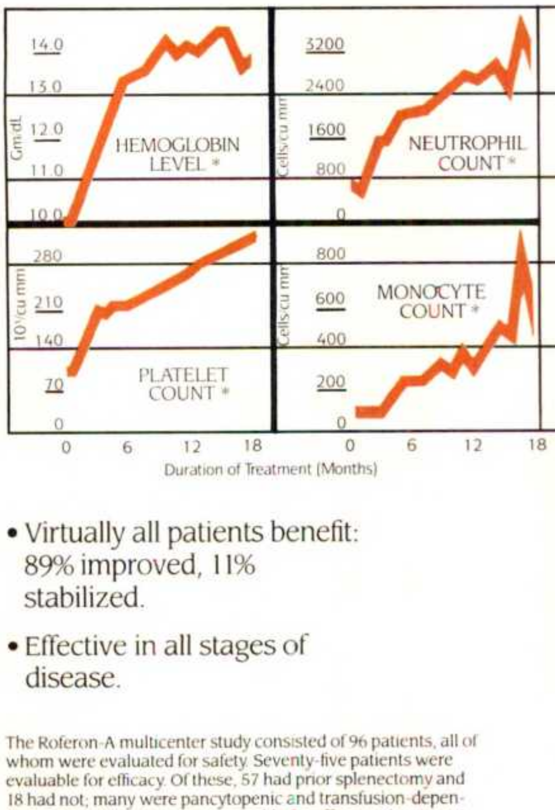
In hairy cell leukemia

Restore normal patterns

Normalize blood parameters

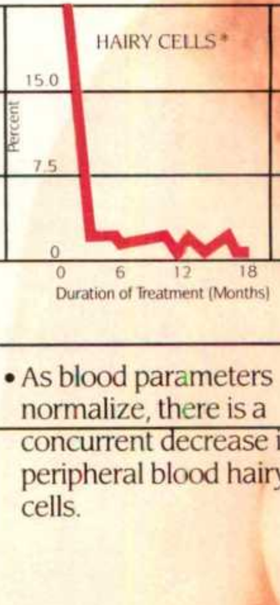


- Virtually all patients benefit: 89% improved, 11% stabilized.
- Effective in all stages of disease.

The Roferon-A multicenter study consisted of 96 patients, all of whom were evaluated for safety. Seventy-five patients were evaluable for efficacy. Of these, 57 had prior splenectomy and 18 had not; many were pancytopenic and transfusion-dependent. Of the 21 patients not evaluable for efficacy, 16 were not on drug long enough for efficacy evaluation at the time of data analysis, 2 were removed for administrative reasons, and 3 were removed for preexisting intercurrent illness.

*Multicenter Study, Data on file, Hoffmann-La Roche Inc., Nutley, NJ.

Reduce tumor burden



- As blood parameters normalize, there is a concurrent decrease in peripheral blood hairy cells.

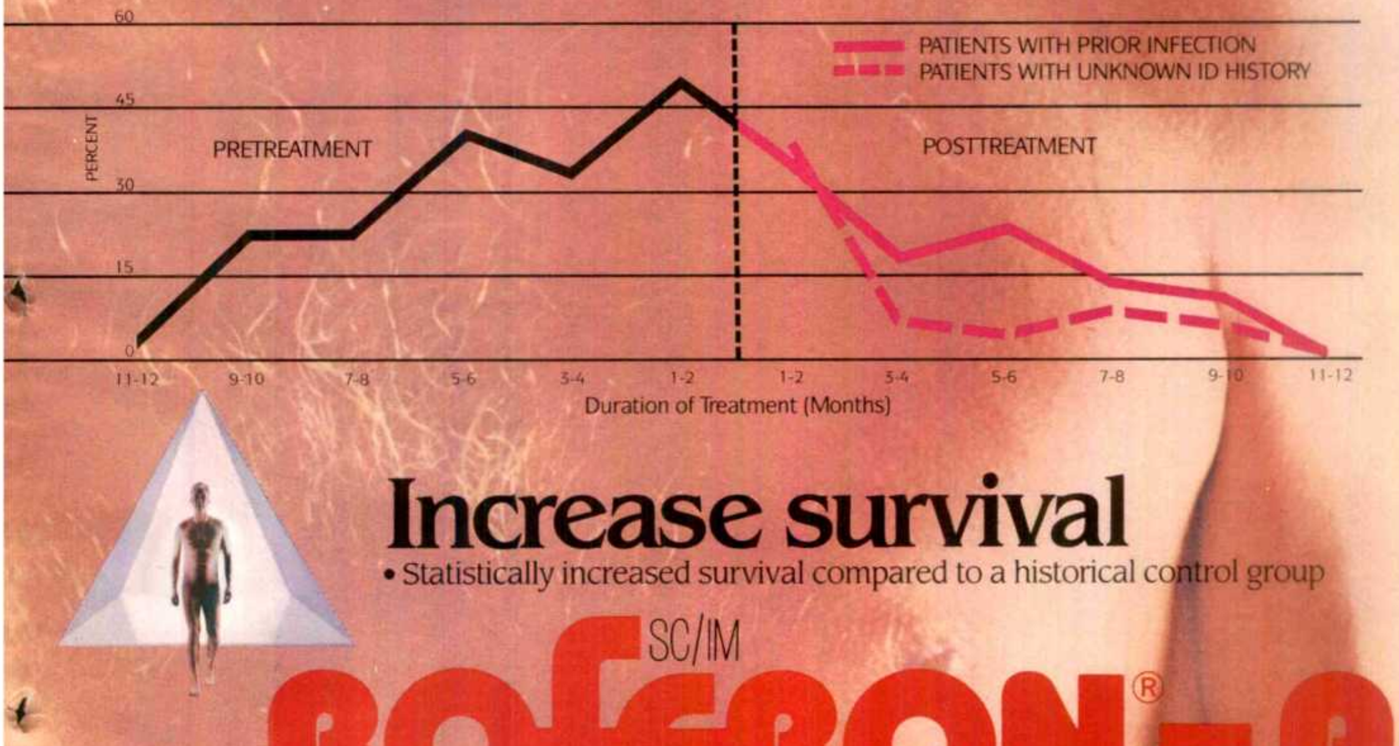
ROCHE Leading the way in biotherapeutics

Copyright © 1987 by Hoffmann-La Roche Inc. All rights reserved.

Virtually eliminate opportunistic infections

- Key disease-fighting elements are restored with normalization of blood counts.

PERCENTAGE OF PATIENTS EXPERIENCING INFECTION*



Increase survival

- Statistically increased survival compared to a historical control group

SC/IM

ROFERON®-A

Interferon BRAND OF alfa-2a, recombinant/Roche

Please see summary of product information on following page.

ROFERON®-A
Interferon alfa-2a, recombinant/Roche

Before prescribing, please consult complete product information, a summary of which follows:

CONTRAINDICATIONS: Hypersensitivity to alfa interferon, mouse immunoglobulin or any component of the product.

WARNINGS: Administer only under guidance of qualified physician. (See DOSAGE AND ADMINISTRATION.) Appropriate management of therapy and its complications is possible only when adequate diagnostic and treatment facilities are readily available.

Use with caution in patients with severe preexisting cardiac disease, severe renal or hepatic disease, seizure disorders and/or compromised CNS function.

Because of the possibility of severe or even fatal adverse reactions, inform patients of both benefits and risks.

Use with caution in patients with cardiac disease or *any* history of cardiac illness. No direct cardiotoxic effect has been demonstrated, but it is likely that acute, self-limited toxicities (*i.e.*, fever, chills) frequently associated with administration may exacerbate preexisting cardiac conditions. Rarely, myocardial infarction has occurred.

Exercise caution in administration to patients with myelosuppression.

CNS adverse reactions included decreased mental status, exaggerated CNS function, dizziness. More severe obtundation and coma rarely observed. Most of these abnormalities were mild and reversible within a few days to three weeks upon dose reduction or discontinuation of therapy. Careful periodic neuropsychiatric monitoring of all patients recommended.

Leukopenia and elevation of hepatic enzymes occurred frequently but were rarely dose-limiting. Thrombocytopenia occurred less frequently. Proteinuria and increased cells in urinary sediment were also seen infrequently. Rarely, significant hepatic, renal and myelosuppressive toxicities were noted.

PRECAUTIONS: *General:* When considering for chemotherapy, evaluate need and usefulness of the drug against risk of adverse reactions. Most adverse reactions are reversible if detected early. If severe reactions occur, reduce dosage or discontinue drug and take appropriate corrective measures. Reinstitute therapy with caution and with adequate consideration of the further need for the drug and alertness to possible recurrence of toxicity.

The minimum effective dose in hairy cell leukemia not established.

Information for Patient: Caution patients not to change brands of Interferon without medical consultation, as a change in dosage may result. Inform patients regarding potential benefits and risks. If home use is desirable, give instructions on appropriate use, including review of the Patient Information Sheet. Patients should be well hydrated, especially during initial stages of treatment.

Laboratory Tests: Complete blood counts and liver function tests should be performed prior to therapy and at appropriate periods during therapy. Since responses are not generally observed for one to three months after treatment initiation, very careful monitoring for severe depression of blood cell counts is warranted during the initial phase.

Patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer should have electrocardiograms taken prior to and during treatment.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Carcinogenesis: Roferon-A has not been tested for carcinogenic potential.

Mutagenesis: A. Internal studies. Ames test results revealed no evidence of mutagenicity. Human lymphocyte cultures were treated *in vitro* at noncytotoxic concentrations. No increase in chromosomal damage noted. B. Published studies. No published studies on mutagenic potential. However, a number of studies on the genotoxicity of human leukocyte interferon have been reported. A chromosomal defect has been reported after the addition of human leukocyte interferon to lymphocyte cultures from a patient suffering from a lymphoproliferative disorder. Other studies have failed to detect chromosomal abnormalities following treatment of lymphocyte cultures from healthy volunteers with human leukocyte interferon. Protection from chromosomal aberrations produced by gamma rays observed in primary chick embryo fibroblasts.

Impairment of Fertility: Nonpregnant female rhesus monkeys treated at doses of 5 and 25 million IU/kg/day have shown menstrual cycle irregularities, including prolonged or shortened menstrual periods and erratic bleeding; these cycles were considered to be anovulatory. Monkeys returned to a normal menstrual rhythm following discontinuation of treatment.

Drug Interactions: Not fully evaluated.

PREGNANCY: Pregnancy Category C. Safe use in human pregnancy not established. Therefore, use during pregnancy only if potential benefit justifies potential risk to fetus. Primate studies showed dose-related menstrual irregularities and an increased incidence of spontaneous abortions. Decreases in serum estradiol and progesterone concentrations reported in women treated with human leukocyte interferon. Therefore, fertile women should not receive Roferon-A unless they are using effective contraception during therapy. Male fertility and teratologic evaluations have yielded no significant adverse effects.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children under 18 not established.

ADVERSE REACTIONS: The following data on adverse reactions are based on the SC or IM administration of Roferon-A as a single agent for the treatment of 63 patients with hairy cell leukemia during investigational trials in the U.S.

Flu-like syndromes consisting of fatigue (89%), fever (98%), chills (64%), myalgias (73%), headache (71%) occurred in the majority of patients and tended to diminish with continuing therapy. Other side effects such as anorexia (46%), nausea (32%), emesis (10%), diarrhea (29%), dizziness (21%), rash (18%), change in taste (13%), dryness or inflammation of the oropharynx (16%), dry skin or pruritus (13%), weight loss (14%) were observed with moderate frequency. Less commonly, diaphoresis (8%), paresthesias (6%), numbness (6%), partial alopecia (8%), reactivation of herpes labialis (8%), transient impotence (6%), arthralgias (5%) were also observed. Rarely (<3%), CNS effects including decreased mental status, depression, visual disturbances, sleep disturbances, nervousness, as well as cardiac adverse events, including hypertension, chest pain, arrhythmias, palpitations, were reported. Adverse experiences which occurred rarely and may have been related to underlying disease included epistaxis, bleeding gums, ecchymosis, petechiae. Miscellaneous adverse events, such as night sweats, urticaria, conjunctivitis, inflammation at the site of injection, were also rarely observed.

Roferon-A has also been evaluated for the treatment of many other types of cancer under investigation in the U.S. These studies generally utilized higher doses (12 to 50 million $\mathrm{IU/m^2}$). All of the above adverse reactions which occurred in patients with hairy cell leukemia were also observed in patients receiving higher doses. The incidence of most adverse reactions was similar between the two groups, but tended to be more severe in the higher dosage group. Additional adverse effects which occurred in these patients included confusion (10%), hypotension (6%), lethargy (3%), edema (3%). Adverse experiences occurring in less than 1% of these patients and observed only in patients with malignancies other than hairy cell leukemia are as follows: *GI:* abdominal fullness, hypermotility, hepatitis; *CNS:* gait disturbance, poor coordination, hallucinations, syncope, seizures, encephalopathy, psychomotor retardation, coma, stroke, transient ischemic attacks, aphasia, aphonia, dysarthria, dysphasia, forgetfulness, amnesia, sedation, apathy, anxiety, emotional lability, irritability, hyperactivity, involuntary movements, claustrophobia, loss of libido; *Peripheral Nervous System:* muscle contractions; *Cardiovascular:* congestive heart failure, pulmonary edema, myocardial infarction, Raynaud's phenomenon, hot flashes; *Pulmonary:* bronchospasm, tachypnea; *Miscellaneous:* excessive salivation, flushing of skin.

Abnormal Laboratory Test Values. The percentages of abnormal laboratory test values seen in 1019 patients evaluated in overall safety trials (including hairy cell leukemia patients) are: *Hematologic:* leukopenia (69%), neutropenia (58%), thrombocytopenia (42%), decreased hemoglobin (6.3%), decreased hematocrit (12.5%); mean time to nadir: WBC—22 days, platelets—17 days. *Hepatic:* SGOT (78%), alkaline phosphatase (48%), LDH (47%), bilirubin (31%). *Renal/Urinary:* BUN (10%), serum creatinine (10%), uric acid (15%), proteinuria (25%). *Other Tests:* hypocalcemia (51%), elevated serum glucose (39%), elevated serum phosphorus (17%).

Neutralizing antibodies were detected in approximately 27% of all patients (3.4% for hairy cell leukemia patients). No clinical sequelae of their presence have been documented. Antibodies may occur spontaneously in certain clinical conditions.

DOSAGE AND ADMINISTRATION: Hairy Cell Leukemia—The dose of Roferon-A is 3 million IU daily for 16 to 24 weeks, administered as an SC or IM injection. SC administration is particularly advisable for, but not limited to, thrombocytopenic patients (platelet count <50,000) or for patients at risk for bleeding. The recommended maintenance dose is 3 million IU, 3 times/week. Dosage reduction by one-half or withholding of individual doses may be needed when severe adverse reactions occur. The use of doses higher than 3 million IU is not recommended. Treatment should be continued for 6 months before determining whether to discontinue therapy in nonresponding patients. The optimal duration of treatment has not been determined in responding patients. If severe reactions occur, modify dosage (50% reduction) or temporarily discontinue therapy until adverse reactions abate. The need for dosage reduction should take into account the effects of prior X-ray therapy or chemotherapy that may have compromised bone marrow reserve.

HOW SUPPLIED: Roferon-A Injectable Solution: Vials containing 3 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/mL). Boxes of 10 (NDC 0004-1987-01). Roferon-A Injectable Solution: Vials containing 18 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/0.5 mL). Boxes of 1 (NDC 0004-1988-09). Roferon-A Sterile Powder for Injection: Vials containing 18 million IU Interferon alfa-2a, recombinant/Roche, with accompanying diluent. Boxes of 1 (NDC 0004-1993-09). For reconstitution, storage and handling directions, see complete product information.

ROCHE®
ROCHE LABORATORIES
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

PI 1086

The promise fulfilled

Restore quality to life

- Performance status greatly improved
- 86% of patients gained up to 10% of, or maintained, their total body weight

Common side effects usually self-limiting and manageable

Initial side effects, such as fever, chills, myalgias, headache and fatigue, are self-limiting and generally manageable. Myelosuppression, which can occur early in the treatment course, warrants close clinical and laboratory observation and is usually alleviated by dose reduction or temporary discontinuation of drug. Roferon-A should be used with caution in patients with severe preexisting cardiac disease, severe renal or hepatic disease, seizure disorders and/or compromised central nervous system function. Persistent fatigue is found to be less troublesome with *p.m.* or *h.s.* administration.

SC/IM fixed dosing simple enough for self-administration

Ready-to-Use Injectable Solution

No mixing or reconstitution necessary

3 million IU vial (3 million IU/mL)

18 million IU vial (3 million IU/0.5 mL)

Sterile Powder for Injection

18 million IU vial (3 million IU/0.5 mL)

3 mL diluent for reconstitution

Must be refrigerated at temperatures of 36° to 46°F (2° to 8°C). At no time should Roferon-A Ready-to-Use Injectable Solution remain unrefrigerated for more than 24 hours. The Sterile Powder for Injection should not remain unrefrigerated for more than 48 hours. Once the powder is reconstituted, it should be refrigerated and must be used within 30 days. Do not freeze or shake.

QUANTITATE FLUORESCENCE

Quantitative Fluorescein Microbead Standards Kit™

Practical applications of flow cytometry demand stable and reproducible results. Now, with our Quantitative Fluorescein Microbead Standards Kits™, fluorescence and size determinations of cells can be compared between laboratories and over time. By using our quantitative kits, you can conveniently determine the fluorescence intensity of fluorescein-labeled cells. Accurate values, independent of instrument, can be achieved, because the excitation and emission spectra of our calibrated fluorescein microbeads match those of the fluorescein-labeled cell samples.

For further information contact:

Flow Cytometry Standards Corporation
PO Box 12621
Research Triangle Park, NC 27709
Phone: (919) 967-9345

FLOW CYTOMETRY STANDARDS CORPORATION™

Only our Quantitative Fluorescein Microbeads have so many unique features and applications:

- *calibrate your instrument for size* to quantitate cell surface area, diameter, cross-sectional area and volume
- *calibrate your instrument for fluorescence* to quantitate the number of equivalent soluble fluorescein molecules per cell
- *determine instrument stability* to reliably and reproducibly measure cell samples over time
- *determine instrument noise level* to know just how sensitive your instrument is
- *choose the calibration range* by selecting either the low level (6,000-50,000 equ. sol. fl. mol/microbead) or high level (60,000-2,000,000 equ. sol. fl. mol/microbead) quantitative kit.

ALSO AVAILABLE:

Fluorescent Microbead Alignment Standards™ whose fluorescent properties match those of stained cells. Our microbeads carry the same dyes used in your research: *FITC, PE, APC, Texas Red, Hoechst, Propidium Iodide, Acridine Orange and more!*

All You Need Is Under One Roof:

Custom designed & manufactured specialized blood processing sets.

LIKE THE NAUTILUS SHELL, ETHOX contains many "chambers", each available to assist you at every stage of the sterile disposable development and manufacturing process. That's why leading organizations rely on Ethox for:

- Custom design & manufacture.
- Experimental & limited production quantities.
- Specialized blood & solution bags.
- Integrated blood tubing & bag sets.
- Blood bag PVC and other biocompatibility-tested and certified materials.

Like the chambered Nautilus shell, a quarter century of Ethox expertise can provide you with the talent, systems, facilities & capabilities in the design, development & manufacturing of specialized blood processing, handling & storage systems.

Call today and ask for our free 22-page color catalog.

Read this like your life depends on it.

Breast cancer found early and treated promptly has an excellent chance for cure. About a week after your period, when breasts are normal, practise this self-exam. Ask your doctor to teach you this method:

1. In bath or shower. Fingers flat, move opposite hand gently over each breast. Check for lumps, hard knots, thickening.

2. In front of a mirror. Observe breasts. Arms at sides. Raise arms high overhead. Any change in nipples, contours, swelling, dimpling of skin? Palms on hips: press down firmly to flex chest muscles. Breasts do not usually match.

3. Lying down. Pillow under right shoulder, right hand behind head. Left hand fingers flat, press gently in small circular motions starting at 12 o'clock. Make about three circles moving closer to and including nipple. Reverse and repeat on left.

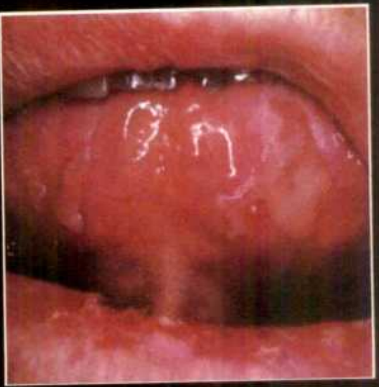
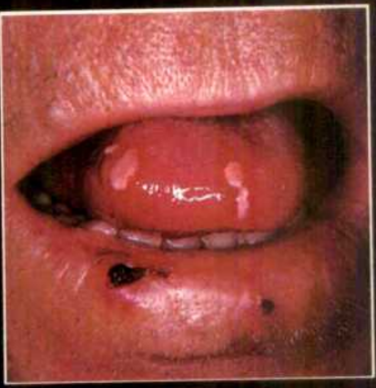
Radiogenic mucositis or herpes simplex?

See answer under flap.

The diagnostic challenge in immunocompromised patients...





Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

ZOVIRAX® I.V.
(acyclovir sodium)
STERILE POWDER/I.V. INFUSION

When the problem begins with a virus, end it with an antiviral.

Please see following page for brief summary of prescribing information.

ZOVIRAX® I.V.
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax (acyclovir sodium) sterile powder is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS*** — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M^2 at a constant rate over 1 hour, every 8 hours (750 mg/M^2/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M^2)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

Paul A. Marks (1978-1982)

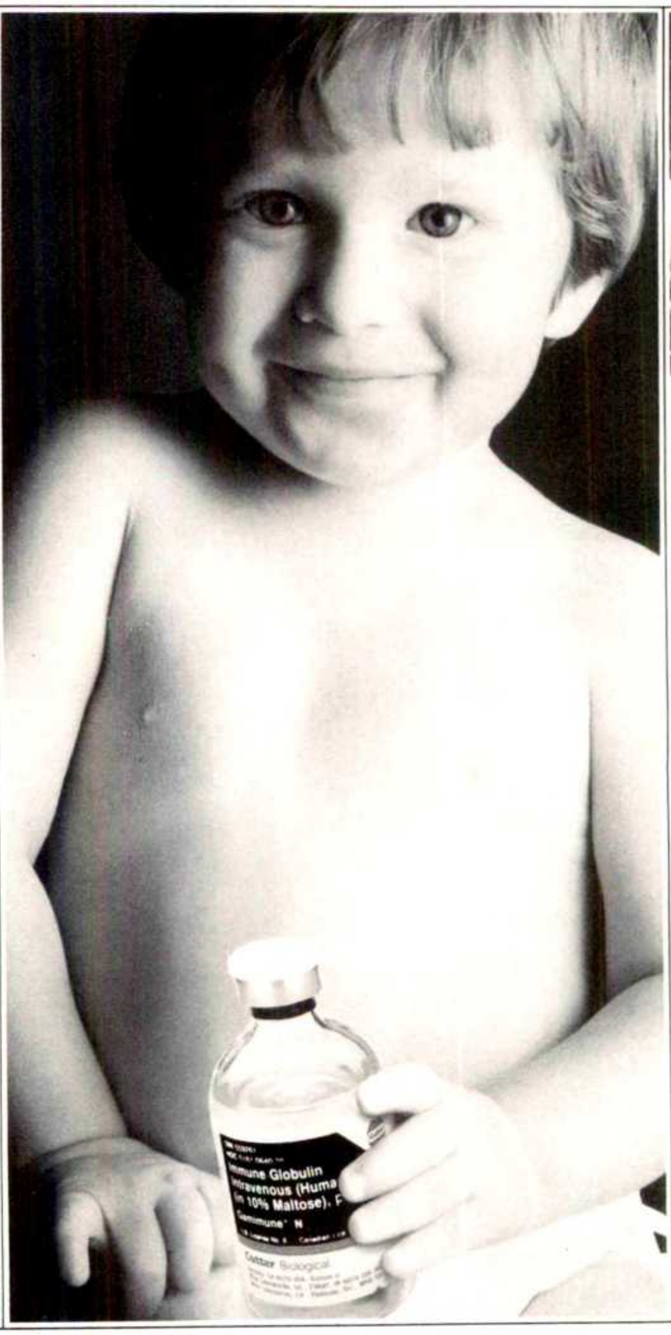
Today's IGIV. Don't settle for less.

For immunodeficiency syndromes: aggressive protection against infection

Patients without sufficient levels of antibodies face overwhelming infection, and they need help. Infusion with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens…in just minutes.

For both chronic and acute ITP in children and adults: rapid elevation of platelet levels

GAMIMUNE® N may initiate a therapeutic increase in platelets in both children and adults with idiopathic thrombocytopenic purpura (ITP).[1*†] Treatment with GAMIMUNE® N has enabled some ITP patients to undergo major surgery.[1]

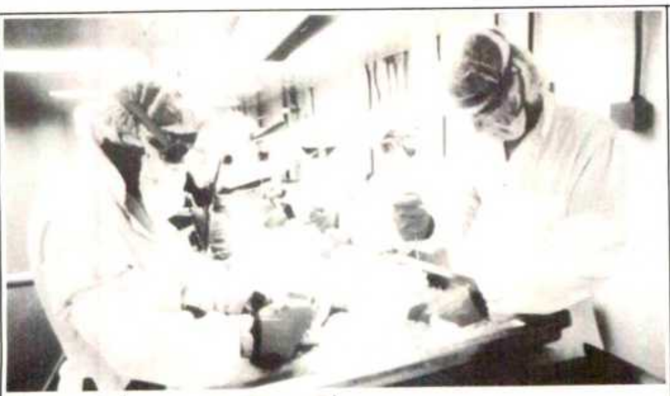


IGIV that's at least 98% pure gamma globulin

Cutter's fractionation method (Cohn-Oncley 6 & 9) contains all the necessary steps to produce high purity immune globulin. GAMIMUNE® N contains no foreign contaminants, no detectable levels of protein aggregates or vasoactive enzymes.[2] With GAMIMUNE® N you get what you expect …IGIV containing at least 98% pure gamma globulin.[1]

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

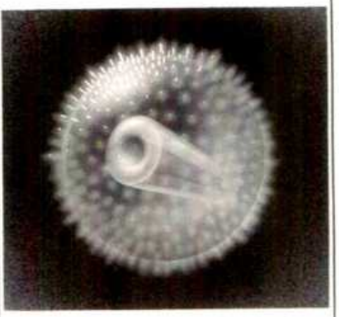


"Native" IGIV

GAMIMUNE® N is manufactured without chemical modification. This means GAMIMUNE® N antibodies maintain normal opsonization capacity, have a normal distribution of IgG subgroups and provide the immunologic activity of normal plasma.[1]

Documented in vitro inactivation of HTLV-III virus[‡]

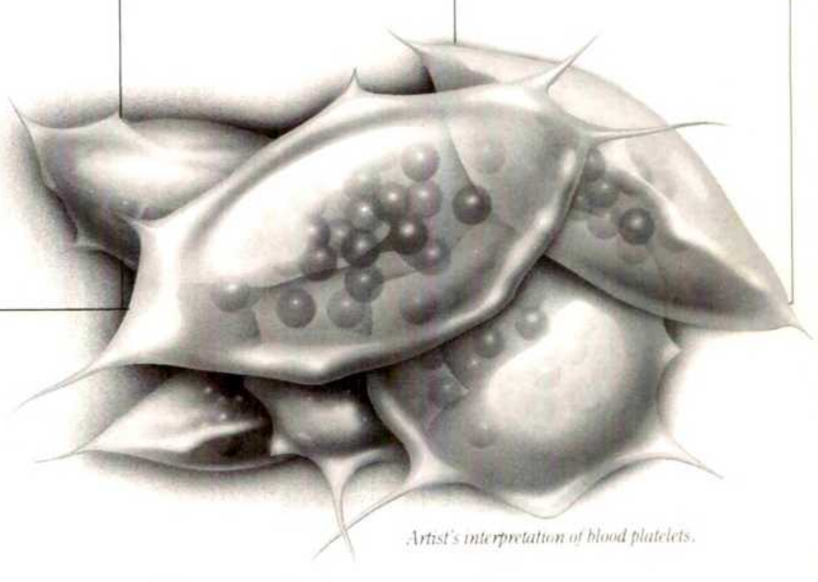
[‡] The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1 x 10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1 x 10^3 to 1 x 10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.[3]



Artist's interpretation of HTLV-III virus.

Today's simple, economical IGIV: the only ready-to-use liquid

Dose for dose, GAMIMUNE® N saves money by eliminating valuable reconstitution time in the pharmacy. Gram for gram of protein, GAMIMUNE® N is affordable; there is no premium price for TODAY'S IGIV.



Artist's interpretation of blood platelets.

---

[*] It is not possible to predict which patients with ITP will respond to therapy.

[†] In patients who respond to therapy, a rise in platelet count is generally rapid (within 1 to 5 days), transient (most often lasting from several days to several weeks) and should not be considered curative.

From the original IGIV, today's IGIV...it offers more

Please see following page for brief summary of prescribing information.

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune® N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune® N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune® N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune® N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune® N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune® N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune® N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: *Gamimune® N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune® N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.*

Idiopathic Thrombocytopenic Purpura (ITP): *Investigations in both children and adults have shown that Gamimune® N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune® N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune® N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune® N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune® N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune® N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune® N treatment.*

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune® N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1–5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune® N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune® N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune® N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune® N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune® N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: *Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.*

Drug Interactions: *If dilution is required, Gamimune® N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune® N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.*

Pregnancy Category C: *Animal reproduction studies have not been conducted with Gamimune® N. It is not known whether Gamimune® N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune® N should be given to a pregnant woman only if clearly needed.*

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune® N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune® N. Symptoms reported with Gamimune® N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune® N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune® N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune® N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune® N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune® N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: *The usual dosage of Gamimune® N for prophylaxis in immunodeficiency syndromes is 100–200 mg/kg (2–4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.*

Idiopathic Thrombocytopenic Purpura: *An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune® N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune® N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.*

Investigations indicate that Gamimune® N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune® N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be ***gradually*** *increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.*

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

A Positive Point About Breast Cancer.

Now we can see it before you can feel it. When it's no bigger than the dot on this page.

And when it's 90% curable. With the best chance of saving the breast.

The trick is catching it early. And that's exactly what a mammogram can do.

A mammogram is a simple x-ray that's simply the best news yet for detecting breast cancer. And saving lives.

If you're over 35, ask your doctor about mammography.

Give yourself the chance of a lifetime.™

Introduction to Leukemia and the Acute Leukemias. Chronic Leukemias. Myeloproliferative Disorders. Monoclonal Gammopathies and Plasma Cell Dyscrasias. Lipid (Lysosomal) Storage Diseases and Histocytoses. The Lymphomas. Bone Marrow. Introduction to Hemostasis: An Overview of Hemostatic Mechanism, Platelet Structure and Function, and Extrinsic and Intrinsic Systems. Quantitative and Qualitative Vascular and Platelet Disorders, Both Congenital and Acquired. Defects of Plasma Clotting Factors. Interaction of Fibrinolytic, Coagulation, and Kinin Systems and Related Pathology. Evaluation of Red Cell Morphology and Summary of Platelet and White Cell Morphology. Laboratory Methods in Hematology and Hemostasis. Glossary.

CLINICAL HEMATOLOGY AND FUNDAMENTALS OF HEMOSTASIS

Balancing theoretical and practical approaches to material, this excellent new textbook gives comprehensive, assessment-oriented coverage to hematology and the fundamentals of hemostasis. A 32 page section containing 245 full-color plates makes this a totally self-sufficient text which *does not require any supplemental Atlas or other materials.*

Requiring no prior knowledge of hematology, this volume offers a variety of organizational features which enable the reader to easily assimilate facts and concepts. You'll find —

- a chapter devoted exclusively to laboratory procedures and diagnoses
- case histories in each chapter correlating pathological lab findings with individual diseases
- outlines preceding each chapter
- a multitude of high-quality, full-color illustrations as well as line drawings and black-and-white photographs
- an extensive index

The many highly-qualified chapter contributors have helped produce a text of unusual authority with a presentation that is carefully balanced between the purely theoretical and the purely procedural.

Edited by **D. Harmening Pittiglio,** PhD, MT(ASCP), Associate Professor, University of Maryland School of Medicine, Program in Medical Technology, Baltimore, MD; Clinical Assistant Professor, Georgetown University, Schools of Medicine and Dentistry, Washington, DC. Consulting Editor: Ronald Sacher, MD, Director, Blood Bank, Georgetown University Medical Center, Washington, DC. With 26 contributors. About 575 pp., 135 black-and-white ill., plus 245 full-color plates. Ready April 1987. About $45.00.

MODERN BLOOD BANKING AND TRANSFUSION PRACTICES

Using a problem-oriented approach, this in-depth guide thoroughly covers theory, principles and procedures of immunohematology, as well as the function of blood, the involvement of Blood Group Antigens and Antibodies, the principles of transfusion therapy and the physiologic mechanisms of blood loss and replacement. Sixteen pages of color plates include superb full color illustrations of agglutination reactions.

Edited by **D. Harmening Pittiglio,** PhD, MT(ASCP). 580 pp. 120 ill., including 16 pp. in full-color. 1983. $32.00.

F. A. DAVIS BLOOD MANUALS

For freshening recall of hematology basics, or for board examination review, these titles are unsurpassed:

Red Cell Manual, 5th Edition
Robert S. Hillman, MD, and **Clement A. Finch,** MD. 162 pp. Illustd. Soft cover. 1985. $9.95.

White Cell Manual, 4th Edition

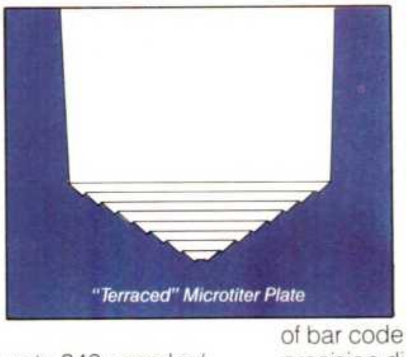
MEET YOUR NEWEST BLOOD BANKER.

THE OLYMPUS PK7100 FULLY AUTOMATED PRETRANSFUSION BLOOD TESTING SYSTEM

Today, with the increased demand in blood testing for transfusion purposes, blood bankers suddenly need new help.

The Olympus PK7100 is the solution. It automatically performs simultaneous routine blood typing (ABO and RH), freeing experienced blood bankers to perform additional tests for the increased incidence of infectious agents (Hepatitis, HTLV-III, etc.).

The PK7100 analyzes up to 240 samples/hour, and features the revolutionary and patented Olympus "Terraced" Microtiter Plate, which reduces reagent consumption and holds cells more firmly in place during less delicate handling. And while the high discrimination PK7100 takes multiple readings on the terraces for extremely accurate automated readings, the terraced plate design provides more stable agglutination/non-agglutination patterns for easy visual confirmation.



"Terraced" Microtiter Plate

And the PK7100 is backed with Olympus' complete support package and extensive field service network.

Other PK7100 features include:
- Full data processing capability: Convenient computerized data storage; Video monitor; High speed printer; RS-232C interface; Triple-check system of bar code labels.
- Micro-syringes (for precision dispensing of serum, blood cells, diluent and reagents).
- Virtually no disposables/consumables.
- Advanced compact design (for easy placement, easy access, and efficient workstation operation).

Blenoxane® ...Integral Component
(sterile bleomycin sulfate)

# of Chemotherapy Regimens in Non-Hodgkin's Lymphoma

Since Blenoxane is virtually non-myelosuppressive, continuing therapy with certain Blenoxane containing chemotherapy regimens (e.g. BACOP) can prevent tumor regrowth between cycles of other chemotherapy regimens while allowing for bone marrow recovery.[*2,3,4,6]

Blenoxane can produce, with cumulative doses, a syndrome of pulmonary fibrosis. It is usually dose-related, being seen infrequently in patients whose total dose of Blenoxane is less than 400 units.

Efficacy... Yesterday, Today, Tomorrow

Blenoxane® *(sterile bleomycin sulfate)*

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{co}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{co} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{co} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain FI O_2 at concentrations approximately that of room air (25%) during surgery and the postoperative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

Coagulation Factor Deficient Human Plasma

- **Substrate Quality**
- **Stable**
- **Fresh Frozen**
- **Mono-Specific**

Announcing

Abnormal and Borderline Assayed Reference Plasma- A-Fact & B-Fact.

COAGULATION DEFICIENCIES AVAILABLE:

Factor I (Afibrinogenemia)
Factor II
Factor V
Factor VII
Factor VIII
Factor VIII Inhibitor
Factor IX
Factor X
Factor XI
Factor XII
Factor XIII
VonWillebrand Trait (Mild and Severe)
Prekallikrein
Kininogen (HMW)
Passovoy Trait
Protein C

HEMATOLOGY PRODUCTS AVAILABLE:

Pooled Normal Plasma
Assayed Normal Plasma
Platelet Free Plasma
Aged Serum
Adsorbed Plasma
Coumadinized Plasma

- Plasmas are fresh frozen, citrated plasmas drawn from carefully screened HUMAN donors with congenital coagulation factor deficiencies.
- Shipments are packed in dry ice and usually delivered within 24 hours.
- Special arrangements are made to ship plasma in required volumes in vials (0.5 to 5.0 ml), in bags or on standing orders.

REVIEW

The Treatment of Hairy Cell Leukemia

By Harvey M. Golomb

IN VIEW OF THE INTRODUCTION of interferon for the treatment of hairy cell leukemia (HCL) in 1984[1] and its release by the Food and Drug Administration for this purpose in June 1986, it is important to consider its use in the context of all of the current indications and options for the treatment of patients with HCL. HCL has been thoroughly studied only for the past 12 years, even though it was first described in 1958 by Bouroncle et al.[2] The morphological, immunologic, and clinical characteristics of this disease have recently been reviewed.[3] It should be emphasized that, at diagnosis, the majority of patients have pancytopenia or multiple cytopenias, a result of the interplay between sequestration of blood in the spleen and underproduction of normal blood cells in the bone marrow. The need to effect a change in one or both sites determines the treatment modality chosen. It should be pointed out, however, that up to 10% of patients require no therapy at any time. Such patients are, on the average, 10 years older than the 52-year median for the whole group, and they have less splenomegaly, fewer circulating hairy cells, and more granulocytes than do other patients with HCL.[4]

TREATMENT

Treatment indications for HCL include severe anemia (hematocrit, <25%) as well as thrombocytopenia (platelet count, <50,000/μL), severe granulocytopenia (absolute granulocyte count, <500/μL), pain or other significant symptoms of splenomegaly, splenic rupture, repeated infections, bone involvement, vasculitis, and bulky retroperitoneal disease. Treatment options have included splenectomy, chemotherapy, leukapheresis, administration of androgens, bone marrow transplantation, radiation therapy, and biologic response modifiers (eg, interferon). There is no useful role for steroids except androgens in the treatment of HCL; when steroids have been given, no improvement in blood cell counts has occurred. Besides, steroids further compromise the immune system of an already abnormal host, thus increasing the risk of infection. Hairy cells have glucocorticoid-binding sites but are resistant to the cytolethal effects of glucocorticoids.[5,6] Another agent whose use should be discouraged is lithium. One patient was reported[7] to have improved hemoglobin levels and platelet counts with lithium therapy, but a subsequent study[8] and our own experience have not supported such a finding.

SPLENECTOMY

Splenectomy has been regarded as an attractive treatment option because it directly addresses the problem of splenic sequestration. However, we have learned that we cannot predict in individual cases whether patients will benefit from splenectomy because spleen size alone is not a direct indicator of postsplenectomy improvement in blood cell counts. In general, enlarged spleens are frequently associated with pancytopenia, and the counts of patients with significant splenomegaly respond more dramatically to splenectomy than is the case for smaller spleens.[9] Even in the absence of splenomegaly, however, significant cytopenia can occur, and it can respond to splenectomy.[10] Recently, we compared the presplenectomy and postsplenectomy blood cell counts of 170 previously untreated HCL patients.[3] The mean hemoglobin level increased from 10.4 g/dL to 11.5 g/dL ($P < .001$), the mean granulocyte count increased from 552/μL to 1754/μL ($P < .001$), and the mean platelet count increased from 87,000/μL to 211,000/μL ($P < .001$). Fewer than 7% of these patients had normal platelet counts before splenectomy; after splenectomy, this percentage rose to 63%. An analysis of the spleen weights of 153 of the 170 splenectomized patients showed that none were normal (<240 g); but of 24 nonpalpable spleens, six weighed between 241 and 400 g and 18 weighed between 401 and 600 g. Thus, approximately one sixth of the patients had nonpalpable spleens that could be two to three times the normal size. Although all HCL patients benefit from splenectomy, slightly less than half of the patients have improvement in all blood cell counts, and improvement in one or two components is seen in the remainder.[9] Moreover, we have updated our original observation that one third of patients require further therapy after splenectomy by showing that almost half (81 of

166 patients) of the patients are in need of additional treatment.[3] The interval after splenectomy until further treatment is required is 1 to 164 months, with a median of 8.3 months.

CHEMOTHERAPY

Progressive disease following splenectomy occurs in two forms; half of the patients have pancytopenia caused by bone marrow replacement with hairy cells, and the other half have a leukemic form of the disease with an increasing white blood cell count (predominantly hairy cells). The latter group may have associated anemia, granulocytopenia, or thrombocytopenia.[11] For the leukemic form of progression, Yam and co-workers initially recommended leukapheresis.[12] Our experience, however, suggests that this does not result in long-term benefit.[13] Of four patients with the leukemic phase of the disease who underwent leukapheresis, two did not respond, and two had transient responses lasting for 1 to 6 months. We no longer utilize leukapheresis in the management of leukemic progression.

Progression with a leukopenic blood count results from underproduction of normal marrow elements secondary to infiltration of the bone marrow by hairy cells. Various types of chemotherapy as well as androgen therapy have been utilized for this form of the disease. In 1979, there were reports of improvement in blood cell counts with use of the alklyating agent chlorambucil in low doses[14] as well as with the drug rubidazone.[15] An update on the efficacy of chlorambucil in 24 HCL patients was published in 1984.[11] Patients were treated for at least 6 months with 4 mg chlorambucil given daily by mouth. Of 11 leukemic patients, all had a considerable dorp in their circulating hairy cells, and seven had increases in their platelet counts, in each case to more than 125,000/μL, following treatment. Of 13 pancytopenic patients, eight had substantially increased platelet counts after treatment; seven also had increased hematocrit values. Half of the patients with pretreatment and posttreatment bone marrow biopsies had objective improvement, as determined by a decrease in the number of hairy cells and an increase in normal marrow elements. However, there were six deaths, all of them associated with infectious complications.

In 1985, Calvo et al[16] reported on seven patients who were treated with intensive chemotherapy consisting of rubidazone, 450 mg/m^2, on day 1; cytosine arabinoside, 200 mg/m^2/d, from day 1 to day 5; and cyclophosphamide, 2,000 mg/m^2, on day 5. A complete response was defined as normal blood counts associated with the disappearance of hairy cell infiltration and fibrosis from the bone marrow. A partial response was defined as normal blood counts with persistence of leukemic cells in the bone marrow. Three patients achieved a complete response and one patient, a partial response. However, three patients died of infectious complications during induction chemotherapy. One patient, who had a complete response, died at 24 months while undergoing maintenance therapy. The remaining responding patients are alive at 44, 32, and 23 months. Joosten et al[17] reported on six HCL patients who relapsed after splenectomy and were treated with high-dose methotrexate (2 g/m^2) and leucovorin rescue. Five patients had objective responses, as determined by improved blood cell counts. The response continued for more than 14 months in one case and 44 months in another; however, these two patients had had the highest absolute neutrophil counts at the start of therapy.

In 1984, Spiers et al[18] reported on the treatment of two HCL patients with pentostatin (2-deoxycoformycin), a product of *Streptomyces antibioticus*. This agent is a tightly binding inhibitor of adenosine deaminase, an enzyme of purine metabolism. Hairy cells were cleared promptly from the blood, splenomegaly and lymphadenopathy regressed, and anemia, thrombocytopenia, and granulocytopenia were corrected. Both patients achieved a complete remission, which continued at 9 and 6 months, respectively, after their last treatment. Johnston et al[19] confirmed the activity of pentostatin in a single patient. At the same time, Spiers et al[20] reported on eight additional patients; three patients attained a complete remission and three were in partial remission (two remained on therapy and may achieve a complete remission). More recently, in 1986, Johnston et al[21] reported eight patients treated with pentostatin. Complete remission occurred in two patients, and four patients had 50% to 95% marrow clearance of hairy cells. Kraut et al[22] reported 10 patients with progressive hairy cell leukemia treated with low-dose pentostatin (4 mg/m^2 IV every other week); nine had a complete remission. Seven patients remained in unmaintained remission with a median duration of 6.2 months. A major advantage of pentostatin is that complete bone marrow remission can be achieved, and may be durable.

HORMONAL THERAPY

Androgens have been used for the treatment of HCL with some success. One study showed that three of six patients who did not benefit from splenectomy responded to androgen therapy, with correction of cytopenia.[23] The responses occurred 1 to 20 weeks after the initiation of therapy and lasted for at least 17 months. A second study[24] concerned a single patient who required an RBC and platelet transfusion after splenectomy. Within 2 months after the beginning of oxymetholone therapy (50 mg orally three times a day), the patient's platelet count had normalized, and improvement in erythocyte and leukocyte counts followed. When the drug therapy was discontinued, the peripheral blood cell counts deteriorated drastically, but they improved when oxymetholone treatment was reinstated. We had a patient who progressed after splenectomy. He did not respond to chlorambucil and continued to require RBC transfusions. Treatment with oxymetholone at the aforementioned dosage led to a normalization of all blood cell counts. The patient has not been receiving oxymetholone for several years and has maintained normal counts.

RADIATION THERAPY

The role of radiotherapy in HCL is limited to the treatment of local problems. Bone involvement has been shown to occur in HCL patients.[25] We have reported six patients who developed hip pain 9 to 73 months (median, 23 months) after the initial diagnosis.[26] As seen on roentgenographs, five patients had single or multiple osteolytic lesions in the proximal portion of the femur, and one patient had no abnormalities. One patient had a concomitant subcapital femoral fracture, and another later developed aseptic necrosis of the proximal parts of the femur and humerus. Five patients were treated with irradiation in doses ranging from 1,500 to 3,000 rad. Three patients completely improved, but two had persistent mild hip discomfort. Orringer and Varia[27] described a patient who developed massive retroperitoneal, abdominal, and mediastinal lymphadenopathy 2 years after splenectomy. Low-dose radiation (600 to 750 rad), given for disabling pain in the back and chest, produced prompt regression of the adenopathy as well as pain relief. The response of patients with these types of local problems suggests that HCL is a radiosensitive disease and that local treatment should be used for local problems.

INTERFERON

The use of α-interferon in the treatment of HCL was first recommended in 1984 by Quesada et al[28] who reported seven patients treated with partially purified leukocyte interferon-α. Granulocytopenia and thrombocytopenia were reversed within several months of therapy. There were three complete responses, and six patients had less than 5% hairy cells in their bone marrows within 8 to 12 weeks.

Because we were following a large group of HCL patients (currently, more than 300 patients), we were able to institute a trial of recombinant α_{2b}-interferon (2×10^6 U/m^2 subcutaneously [SC] three times per week) in October 1983. In eight evaluable patients, we also obtained dramatic results, with seven partial responses,[29] which confirmed that interferon was the active agent. Foon et al[30] recently published their results for 15 patients treated with α_{2a}-interferon, which differs from the α_{2b} form only in the amino acid at position 23. Patients were treated with 3×10^6 units daily either intramuscularly (for platelets $>50{,}000/\mu L$) or SC (for platelets $<50{,}000/\mu L$). They noted one complete response and 12 partial responses for a response rate of 87%. Coincident with the normalization of peripheral blood counts, natural killer cell activity returned, and immunologic surface markers became normal. Comparable results have been obtained with a highly purified polyclonal interferon-α preparation from lymphoblastoid cells.[31]

Quesada et al[32,33] recently summarized their experience in treating 52 HCL patients with interferon; 22 had received leukocyte interferon-α and 30, α_{2a}-interferon. There were five complete, 13 partial, and four minor responses among the 22 patients and five complete, 17 partial, and six minor responses among the 30 patients. The total complete and partial response rate was thus 77%, and the overall response rate was 96%. Six patients had splenomegaly and were candidates for splenectomy, but they elected to have α-interferon as primary therapy. In all six patients, the size of the spleen decreased rapidly (within seven to 15 days). Five of the six obtained a complete remission, compared with four of 24 patients on whom a splenectomy had been performed prior to interferon therapy. Thus, the efficacy of α-interferon in previously untreated patients was demonstrated.

A multicenter study of 64 HCL patients treated with α_{2b}-interferon was recently published by Golomb et al.[34] Three patients (5%) had a complete response, with apparent eradiction of hairy cells from the bone marrow; 45 patients (70%) had a partial response, defined as normalization of all three blood cell counts and decreased HCL involvement in the bone marrow; and nine patients (14%) had a minor response that included improvement in a least one blood cell count. Thus, the overall response rate was 89%. Three patients had no response, three patients died before completing 1 month of therapy, and one patient refused further therapy after being treated for 1 month. A rapid return of a normal platelet count (within 2 months) was confirmed; the hemoglobin and granulocyte counts returned more slowly (within 4 and 5 months, respectively). Subsequent bone marrow biopsy analyses showed a decrease in the hairy cell index by more than half. Serious infections, which had averaged four per month in 16 of the 64 patients before interferon therapy, occurred only rarely after the first month of treatment. Treatment-induced toxic effects were mild and consisted of influenzalike symptoms, fatigue, and minor skin disorders.

The same group has prepared an updated evaluation of the first 128 HCL patients treated with α_{2b}-interferon.[35] The responses obtained were almost identical to those for the first 64 patients. There were five complete responders (4%), 98 partial responders (77%), and nine minor responders (7%). The overall response rate is thus at 88% for the 128 patients. In contrast to Quesada's[32] group of previously untreated patients who had significant complete responses, the patient group[35] includes 13 patients who had not undergone splenectomy; but none of these were complete responders. The discrepancy between the two reports remains to be explained.

Thus, the percentage rate of response to recombinant α-interferons is very high in a large number of patients. This finding led to approval, in June 1986, of recombinant α-interferon by the FDA for prescription for HCL patients by practicing physicians. It is important that the exact role of α-interferon in HCL be understood.

Two groups of investigators recently addressed the objective changes in the peripheral blood and bone marrow of HCL patients who were treated with recombinant α-interferon. Naeim and Jacobs[36] studied blood and bone marrow specimens from 21 patients. Bone marrow samples at 3 months after initiation of interferon therapy showed a decrease in cellularity from 77% to 57%, with a marked decrease in the percentage of hairy cells (87% to 59%). Increased amounts of reticulin fibers persisted after completion of interferon therapy, as did a high incidence of dry taps. They found that with interferon therapy the tartrate-resistant acid phosphatase (TRAP)-positive HCL cells became TRAP-negative, thus suggesting inhibition of activity and/or production of TRAP in HCL cells. Bardawil et al[37] studied specimens from 12 patients. When they examined the patients after 6 to 12 months of interferon therapy, they found that the median hairy cell index had decreased from 0.56 to 0.12; but in no case were hairy cells completely absent from the bone marrow. The numbers of large granular lymphocytes increased in 11 of the 12 patients after interferon therapy, but the numbers often fluctuated, and in three patients they later fell to preinterferon values.

It is important to begin an assessment of the durability of response in patients after interferon therapy is discontinued. Two groups of investigators are attempting to do this. Quesada et al[33] observed a clinical relapse in eight of 25 patients (33%) in whom treatment was discontinued after 12 months. The clinical relapse occurred within 3 to 10 months (median, 6 months) after cessation of treatment in six patients who attained partial remission and one patient each with a complete remission and minor response. Ratain et al[38] have studied 24 patients who completed interferon therapy a median of 8.5 months (range, 3 to 16 months) previously. Only one patient has required further treatment. However, in general there was a marked decrease in normal marrow elements and a relative increase in peripheral blood counts. Clearly, more patients need to be observed closely over a longer period.

In our multicenter study,[35] we attempted to address the issue of duration of therapy and durability of response. A group of patients completing 12 months of interferon therapy and having a minor, partial, or complete remission was randomized to an additional 6 months of interferon therapy or to observation alone. A very preliminary analysis reveals six of 35 patients (17%) randomized to observation alone have relapsed, whereas only two of 29 (7%) in whom interferon therapy was continued have relapsed. Twenty-seven responding patients remained off interferon treatment for 6 months or more. Thus, it has been demonstrated that cessation of interferon therapy does not result in a rapid deterioration of peripheral blood counts. The number of relapsing patients is still too small, however, to allow significant conclusions.

A few HCL patients have not responded to α-interferon. The question arises whether they can respond to pentostatin. Foon et al[39] recently reported two patients with massive splenomegaly and severe pancytopenia who had no significant response in a trial of α_{2a}-interferon. Subsequent treatment with pentostatin for 8 consecutive weeks resulted in normalization of spleen size, peripheral blood cell counts, and bone marrow in one patient. The second patient had a reduction in spleen size and improved blood cell counts following 9 weeks of pentostatin therapy. We have recently observed a patient whose disease progressed during his 14th month of α_{2b}-interferon therapy. He did not respond to treatment for 2 months with γ-interferon and remained dependent on platelet transfusions. Six courses of pentostatin (4 mg/m^2 intravenously every 2 weeks) therapy led to eradication of the hairy cells in the bone marrow and a return to normal peripheral blood cell counts. It thus appears that pentostatin can be effective in patients whose disease has progressed during α-interferon therapy.

RECOMMENDATIONS

What can we conclude from the published and about-to-be-published information with regard to the treatment of patients with HCL? In my opinion, after the correct diagnosis of HCL has been made, one must attempt to identify the 10% of elderly patients who have adequate blood counts and a nonpalpable spleen and who require no treatment. The remaining 90% of patients will usually require some form of therapy within a short period after the diagnosis. For a patient with an easily palpable spleen, low blood counts, and a bone marrow that shows only patchy involvement, a splenectomy should be undertaken as the first choice of treatment. The probability is high that the peripheral blood counts will improve and that the patient might require no further therapy for many years. For a patient with a nonpalpable spleen, low blood cell counts, and a diffusely involved bone marrow, systemic therapy is the first choice. Such patients probably gain little benefit from splenectomy, and they will require systemic therapy within a short time after splenectomy. For a patient who fits between these two categories, either option is reasonable, and both options should be considered and discussed with the patient.

The type of systemic therapy chosen for the presplenectomy patient who will benefit from it or for the postsplenectomy patient who has progressive disease and requires it depends on the following considerations. Interferon is highly active in HCL, with a high response rate, but it results in a low percentage of complete remissions. However, it controls the disease very well and leads to reversal of the clinical problems. Cessation of interferon therapy does not bring about a rapid deterioration of peripheral blood cell counts. Furthermore, a response can be reinduced in the majority of patients requiring retreatment, and the toxicity is mild by comparison with most forms of standard chemotherapy. Pentostatin has been tested in fewer patients; however, it yields a much higher complete response rate and requires only 3 months of therapy as compared with 12 months recommended for interferon. The duration of complete remission is excellent, but the toxicity in terms of the immediate effect on renal and liver function and the delayed effect on immune function remains to be determined.

A randomized trial of pentostatin and α-interferon in postsplenectomy patients with progressive disease is currently under way by the Cancer and Leukemia Group B (CALGB). From the results it should be possible to draw conclusions about the aforementioned concerns. It should also be restated that α-interferon is now available clinically (as of June 1986), whereas pentostatin is not (and is tightly controlled by the National Cancer Institute). However, pentostatin is available through a national cooperative group (CALGB) for HCL patients who have failed α-interferon therapy.

Thus, for patients not being entered into clinical trials, I recommend that α-interferon be used as the first systemic treatment of choice until more data on pentostatin become available regarding its efficacy and toxicity in HCL patients. Also, because pentostatin is effective in patients who have not responded to α-interferon, its benefits can still be utilized by patients initially treated with interferon. Thus, in the event that pentostatin becomes the first agent of choice for systemic treatment of HCL in the future, current patients with progressive disease will have received its therapeutic benefits.

Chromosome Aberrations and Clinical Features of Adult T Cell Leukemia-Lymphoma Not Associated With Human T Cell Leukemia Virus Type I

By Masanori Shimoyama, Tatsuo Abe, Kanji Miyamoto, Keisuke Minato, Kensei Tobinai, Haruhisa Nagoshi, Motoyoshi Matsunaga, Takeo Nomura, Teruhiko Tsubota, Taisuke Ohnoshi, Ikuro Kimura, and Keiichi Suemasu

Chromosome aberrations and clinical features of three patients with adult T cell leukemia-lymphoma (ATL) not associated with human T cell leukemia virus type I (HTLV-I) are described. From their clinical features, two patients were diagnosed as acute type and one patient was diagnosed as chronic type, which later converted to acute crisis. Clonal and many chromosomal abnormalities were observed before therapy in the two acute type cases and at relapse in the chronic type case. Karyotype aberrations, including trisomy 3, trisomy 7, trisomy 21, del(6)(q21), del(10)(p13), 14q11 translocation, and loss of X chromosome, all of which are frequently found in HTLV-I associated ATL, were also seen in these cases of HTLV-I–negative ATL.

© 1987 by Grune & Stratton, Inc.

WE SHOWED in 1983 that some patients with ATL have typical clinicohematologic, morphological, and immunophenotypic features, but test negative for antibody to human T cell leukemia virus type I (HTLV-1).[1] By Southern blot analysis, we recently proved that HTLV-1 was not associated in five patients with anti–HTLV-I antibody-negative ATL.[2] These findings suggested that HTLV-1 may not be involved in leukemogenesis of some ATL patients. To examine leukemogenesis and the exacerbation process of such ATL patients, we conducted karyotype analysis of the leukemia cells. We present evidence that chromosome abnormalities similar to those found in typical HTLV-1-associated ATL were also found in HTLV-1–negative ATL.

MATERIALS AND METHODS

Patients. Previously,[2] we confirmed that any nucleotide sequences of the provirus genome of HTLV-I were not integrated into DNA of leukemia cells from all five patients with anti–HTLV-I antibody-negative ATL. In these patients, the leukemia cells had flower cell morphology as well as the inducer/helper phenotype, both of which are characteristics of ATL.[3-6] Karyotype analysis could be made in the leukemia cells from three of the five patients with HTLV-I–negative ATL. The patients were classified according to clinical subtypes of ATL, as described elsewhere.[4-7]

Cytogenetics. Cytogenetic studies were done on specimens of peripheral blood and pericardial effusion which were obtained before therapy and at relapse. Mononuclear cells prepared from these sources by the usual Ficoll-Hypaque gradient method were examined according to conventional techniques[8] after culturing for 18 to 48 hours without mitogens such as phytohemagglutinin or T cell growth factor. After hypotonic treatment with KCl (0.075 mol/L) for 20 minutes, the cells were fixed in methanol acetic acid (3:1), dropped onto glass slides, and air dried. Conventional Q-banding and/or Giemsa techniques were applied to the slides. Metaphase and prometaphase cells were photographed and then arranged according to the International System for Human Cytogenetic Nomenclature (ISCN).[9] The criteria adopted at the First International Workshop on Chromosomes in Leukemia[10] were used to identify abnormal clones. Karyotypes of cases 1 and 2 were determined after complete reviews by expert members of ATL Karyotype Review Committee—1985.

RESULTS

Clinical features. The clinical features of the three patients with HTLV-1–negative ATL are summarized in Table 1. The age at onset of the disease ranged from 43 to 71 years. There were two men and one woman. Two patients (cases 1 and 2) became acutely ill, and their symptoms at onset were subfever, lymph node swelling, skin rash, and hepatosplenomegaly. Leukemic manifestation and high serum LDH levels were also observed. Pulmonary infiltration of leukemia cells developed later. The patients died of the disease 3 and 11 months, respectively, after the diagnosis (Table 1). In another patient (case 3), leukocytosis due to abnormal inducer/helper T lymphocytosis of flower cell morphology was accidentally found when the patient complained to his physician of dizziness due to iron-deficiency anemia. His T lymphocytosis remained unchanged for ~2 years without specific therapy and then converted to acute phase. Skin lesions, lymph node swelling, hepatosplenomegaly, pulmonary infiltration, pleural effusion, and pericardial effusion developed. Hypercalcemia developed later, and the patient died of cardiac insufficiency 34 months after the diagnosis and 3 months after the acute transformation (Table 1).

Hypercalcemia was observed in two patients. Immunoglobulin levels were found to be within the normal range at onset of the disease in all three patients. Combination chemotherapies, including vincristine, cyclophosphamide, prednisolone, and doxorubicin (VEPA[11] or CHOP[12] therapy), were effective. Two patients were induced into remission, but the effect was transient. From the clinical features,

PB, peripheral blood; PE, pericardial effusion.

*Cytogenetic study was performed at relapse.

t(5;12)(q22;q14) were found in addition to three marker chromosomes (Fig 2A). Chromosome constitution obtained at relapse showed almost the same as that obtained before therapy. But, a translocation involving an X chromosome-t(X;6)(q12;p22)-was newly found, suggesting clonal evolution (Fig 2B). On the other hand, in case 3, the karyotype remained apparently normal, and no gross abnormality was found before therapy. At relapse, however, cells in the pericardial effusion also showed very complicated karyotypes (Fig 3A and B). Two abnormal clones were determined, one of which had a missing Y and partial trisomy 7 (Fig 3B). Many rearranged chromosomes, including del(3)(p12), del(6)(q21q23), del(10)(p13), +der(11)t(11;?)(p15;?), +der(21)t(17;21)(q11;p13) were common to each other, however, suggesting that both cell lines originated from the same progenitor cell. Thus, all three patients had complicated chromosome constitutions, although their modal numbers were near-diploid range. Abnormalities common to three patients were not detected. Abnormalities similar to those found in HTLV-I–associated ATL[13-25] were also found in these three cases of HTLV-I–negative ATL, however.

DISCUSSION

We present the chromosome aberrations and clinical features of three patients with ATL not associated with HTLV-1. These findings and the hematologic, pathologic, and immunophenotypic features of these cases as reported elsewhere[2] are identical to those of HTLV-1–associated ATL.[4-7] The patients in this report are the same as the patients in the previous report,[2] in which we proved that the patients showed neither integration of the HTLV-I proviral genome into chromosomal DNA of leukemia cells nor anti–HTLV-I antibody in serum. In addition, no anti–HTLV-I antibody was detectable in any family members. These facts indicate that HTLV-I was not associated with leukemogenesis in any of these cases of ATL, but we could not exclude the possible presence of a small amount of anti–HTLV-I antibody and of a very small fragment of the HTLV-I provirus that could not be detected with current techniques. Diversity in the clinical course of HTLV-I–associated ATL has been reported.[4-7] Like HTLV-1–associated ATL, there was also diversity in the clinical course of HTLV-1–negative ATL, ie, acute type and chronic type were observed in HTLV-1–negative ATL in this series.

Clonal and many chromosomal abnormalities are documented for HTLV-I–associated ATL by karyotype analysis.[13-19,24,25] Rowley and colleagues[25] reported that trisomy for chromosomes 3 and 7 or 7q, and monosomy for X chromosome, 14q+, and 6q− were noted as the most common abnormalities in ATL, but 14q+ abnormality was not identified in any of the Caribbean ATL patients. Recently, karyotype analysis by the ATL Karyotype Review Committee—1985 of 78 ATL patients from 13 institutions in Japan revealed that +3, +7, -X rearrangements involving 6q15, 6q21, 10p11–13, 14q11, and 14q32 were the most common abnormalities in ATL.[26] In the early phases of ATL, however, such as in smoldering ATL,[4-7] or in chronic ATL,[5,7] minimal chromosomal abnormalities have been reported.[18,20]

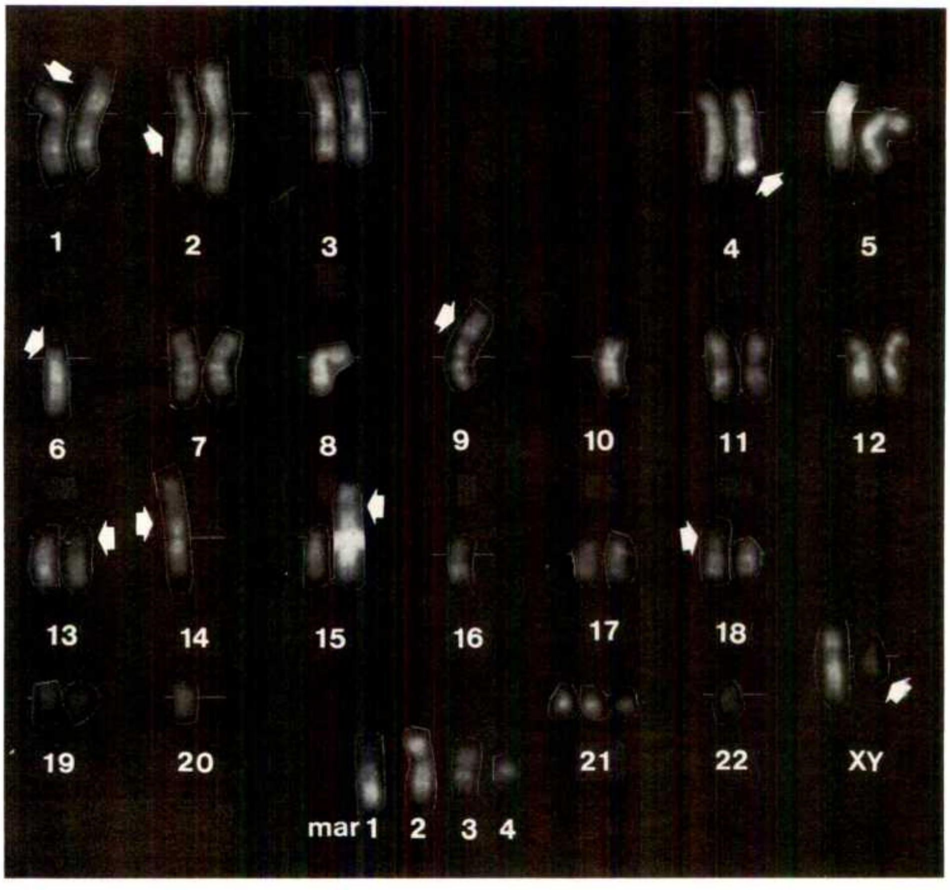

Fig 1. Q-banded karyotype of a leukemia cell from case 1. Exact karyotype is shown in Table 2(a).

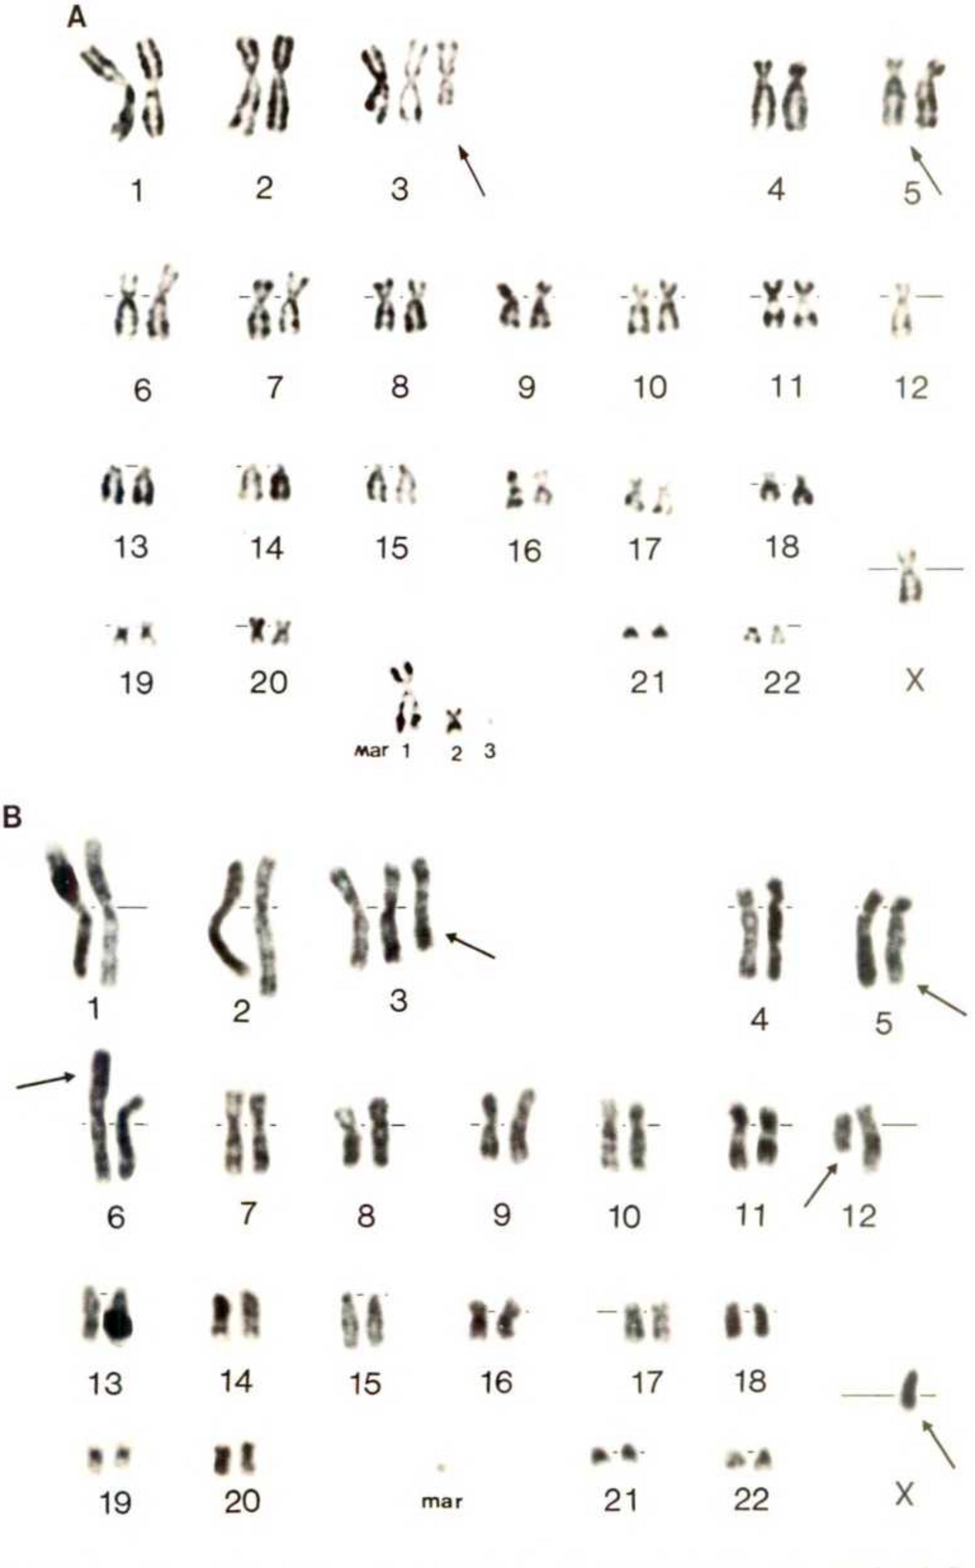

Fig 2. G-banded karyotype of a leukemia cell from case 2. (A) Before therapy. Exact karyotype is shown in Table 2(c). (B) At relapse. Exact karyotype is shown in Table 2(d).

As presented here, in acute HTLV-1–negative ATL, clonal and many chromosomal abnormalities were observed. In chronic HTLV-1–negative ATL (case 3), no chromosomal abnormalities were found at chronic phase, but clonal and many abnormalities, including del(6)(q21q23), +der(7)t(7;?)(q22;?), and del(10)(p13), were found at relapse. In case 1, abnormalities involving the proximal portion of chromosome 14, +der(1)t(1;14)(q13;q11) were found. Recently, abnormalities involving 14q11-q13 have been increasingly reported in various T cell malignancies, including ATL.[16,19,21-23,26,27] In case 2, trisomy for chromosome 3, +der(3)t(3;?)(q12;?), and monosomy for X chromosome were observed. From these cytogenetic findings, it is speculated that HTLV-1–negative ATL cells also have chromo-

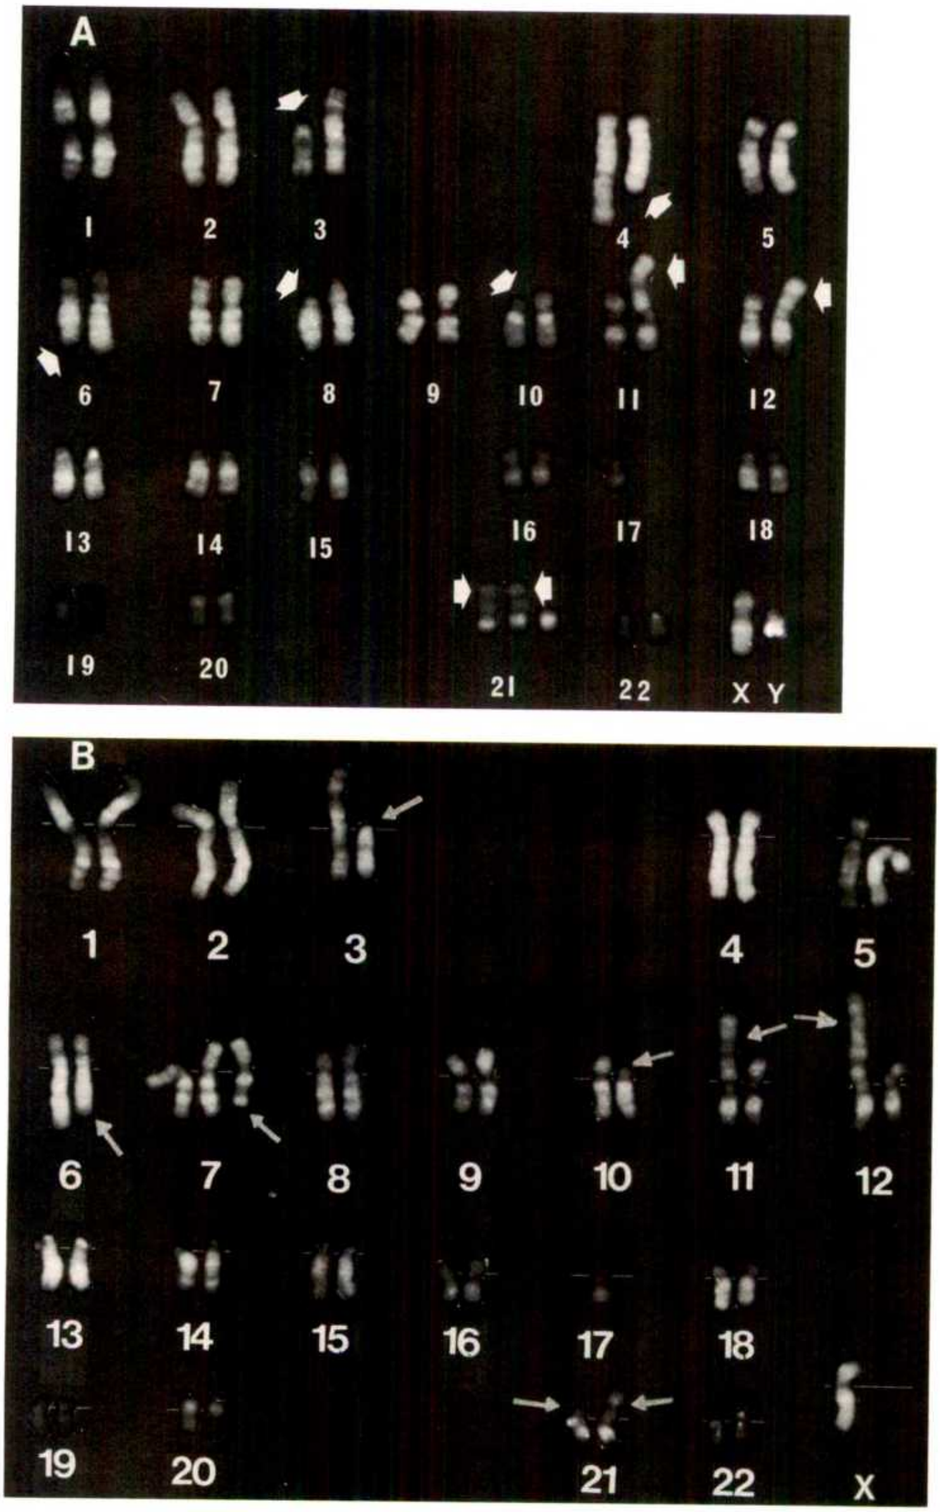

Fig 3. Q-banded karyotype of a tumor cell in pericardial effusion of case 3. Two clones, A and B, were observed. Exact karyotypes of clones A and B are shown in Table 2(f) and 2(g), respectively.

somal abnormalities similar to those reported in HTLV-1–positive ATL or other T cell malignancies.

The number of HTLV-I–negative ATL cases reported is very small, indicating a need for close scrutiny of this disease. Results indicate no detectable differences between the clinicohematologic, cytopathologic, immunologic, and karyotype features of HTLV-1–positive and HTLV-1–negative ATLs. The findings of HTLV-1–negative ATL suggest that there is a similar underlying mechanism(s) in leukemogenesis as well as in the malignant process of both HTLV-I–related and HTLV-I–unrelated ATL. The presence of HTLV-1–negative ATL suggests the existence of unknown cellular oncogenes closely related to the transformation of inducer/helper T cell. We consider the role of HTLV-I in the etiology of ATL to be similar to that of Epstein-Barr virus in Burkitt's lymphoma. The causative agent of ATL may not always be

HTLV-I; hence, the disease entity of ATL may not always be defined as an HTLV-I–induced T cell malignancy.

Establishment and Characterization of a Cell Line, TOM-1, Derived From a Patient With Philadelphia Chromosome–Positive Acute Lymphocytic Leukemia

By Mihiro Okabe, Shozo Matsushima, Masanobu Morioka, Masanobu Kobayashi, Shuichi Abe, Keisuke Sakurada, Mitsuaki Kakinuma, and Tamotsu Miyazaki

A new Philadelphia chromosome (Ph^1)-positive cell line, designated TOM-1, was derived from bone marrow cells of a patient with Ph^1-positive acute lymphocytic leukemia (ALL). The TOM-1 cells were positive for Ia and B1 antigens and terminal deoxynucleotidyl transferase (TdT) but negative for common ALL antigen. Although neither surface Ig nor cytoplasmic Ig was detected, the TOM-1 cells contained rearranged immunoglobulin-H chain genes but retained germ-line κ chain and germ-line T cell receptor β-chain genes. These results indicate that the TOM-1 cells reside as the progenitor of pre-B cells. We have investigated the chromosome 22 breakpoint and c-*abl* gene expression in the TOM-1 cells. We found that the breakpoint on chromosome 22 was within the breakpoint cluster region (*bcr*) in the TOM-1 cells. We also found the breakpoints within or near *bcr* in four of six Ph^1-positive ALL cases, similar to the findings in Ph^1-positive CML cases. Amplification of the c-*abl* gene was not detected in the TOM-1 cells. The leukemic cells isolated from a patient with CML in myeloid crisis contained a novel 8-kilobase (kb) *abl*-related messenger RNA (mRNA), but the TOM-1 cells contained c-*abl* transcripts of only normal sizes, despite the fact that they showed the *bcr* gene rearrangement.

© 1987 by Grune & Stratton, Inc.

THE PHILADELPHIA (Ph^1) chromosome is a typical cytogenetic abnormality observed in chronic myelogenous leukemias (CML).[1] However, the Ph^1 chromosome has also been observed frequently in acute lymphocytic leukemias (ALL),[2,3] since Propp and Lizzi reported a case of Ph^1-positive ALL.[4]

It has been generally accepted that the development of cell lines derived from various types of hematopoietic disorders may offer the means by which to resolve the pathophysiology of the diseases. Several Ph^1-positive leukemia cell lines have been established from patients with CML in blastic crisis[5-7] and have offered opportunities for analysis of the molecular events accompanied by the t(9:22) translocation.[8,9]

It has been reported that, in CML cells, the c-*abl* gene translocated from chromosome 9 to chromosome 22 and aberrant 8-kb c-*abl* mRNA, longer than that of normal counterparts, was transcribed.[9-11] In CML the breakpoints on the chromosome 22 cluster are within approximately a 5.8-kb segment, which is referred to as breakpoint cluster region (*bcr*).[10] These findings strongly suggest the role of c-*abl* and *bcr* genes in the pathogenesis of CML. At present it is unknown whether or not the breakpoint on chromosome 22 and the abnormal expression of the c-*abl* gene found in the CML cells can be extended to Ph^1-positive ALL.

We have established a new leukemic cell line, designated as TOM-1, from a patient with Ph^1-positive ALL. This cell line, as far as we are aware, is the first cell line derived from a Ph^1-positive ALL patient. This cell line was identified as the progenitor of pre-B cells, as revealed by analyses of cell surface antigens and Ig gene rearrangements. We report here *bcr* gene rearrangement and expression of c-*abl* gene in the TOM-1 cells.

CASE REPORT

A 54-year-old female was referred to the Department of Internal Medicine, Kanazawa Medical College, on September 9, 1983, displaying marked leukocytosis (WBC count: 42.5 × 10^9/L). The diagnosis was ALL, which phenotypically was Ia-positive and common ALL antigen (CALLA)-positive. She then received combination chemotherapy with vincristine, cyclophosphamide, Adriamycin (doxorubicin, Farmitalia, Milan, Italy) and Predonin (prednisolone, Schering, Kenilworth, NJ); but remission was not achieved. She was referred to our hospital on November 14, 1983. On admission, her peripheral blood examination revealed RBC count 415 × 10^{10}/L and WBC count 8.2 × 10^9/L with no appearance of leukemic cells. The bone marrow aspirate showed hypercellular marrow (nuclear cell count: 85.9 × 10^{10}/L) consisting of 89.7% leukemic cells. The Ph^1 chromosome was identified in all bone marrow cells analyzed. In May 1984, complete remission was achieved after MOAD therapy: moderate-dose methotrexate, vincristine, asparaginase, and dexamethasone.[12] At that time the Ph^1 chromosome was not detected in bone marrow or peripheral blood cells. After remission was achieved, a transversion into chronic CML was not found. However, the patient relapsed and died of respiratory failure due to bacterial pneumonia in July 1984.

MATERIALS AND METHODS

Culture of leukemic cells. Heparinized blood was taken by bone marrow aspiration from the patient on November 14, 1983. Mononuclear cells were separated by Ficoll-Hypaque density sedimentation, washed twice, and suspended in complete medium; RPMI 1640 was added with 10% fetal bovine serum, 2 mmol/L L-glutamine, 25 mmol/L Hepes buffer, 100 U/mL penicillin G, and 100 μg/mL streptomycin. The leukemic cells were cultured in tissue culture plastic flasks in humidified atmosphere added with 5% CO_2 at 37 °C.

Cytochemistry. Staining with periodic-acid Shiff (PAS), peroxidase, acid phosphatase, Sudan Black B (SBB), α-naphthyl butylate esterase (α-NBE), and naphthol AS-D chloroacetate esterase (NACE) was performed on primary and established leukemic cells.

Phenotypical analysis. Surface immunoglobulin (sIg) and cytoplasmic immunoglobulin (cIg) were analyzed by direct immuno-

fluorescence methods. Fluorescein isothiocyanate (FITC)-labeled goat F(ab)$'_2$ antihuman immunoglobulin was purchased from Cappel Laboratories, Cochranville, PA. Subset and/or stage-specific surface markers were analyzed by an EPICS C flow cytometer (Coulter Electronics, Hialeah, FL) using commercially available monoclonal antibodies (MoAbs) and FITC-labeled F(ab)$'_2$ fragment of goat antimouse IgG antibody (Cappel Laboratories). The MoAbs J-5,[13] OKIa1,[14] OKB1,[15] OKB2,[16] OKT3,[17] OKT4,[17] and OKT8[17] were purchased from Ortho Pharmaceutical, Raritan, NJ. Terminal deoxynucleotidyl transferase (TdT) activity was assayed by the method of Hoffbrand et al[18] and was given as units per 10^8 cells where 1 unit equaled to 1 nmol of substrate polymerized per hour. Epstein-Barr nuclear antigen (EBNA) was assayed by the anticomplement immunofluorescence method as described by Reedman and Klein.[19]

Chromosomal analysis. The cells were cultured in the presence of colcemide for one hour before harvesting, resuspended in 0.075 mol/L KCl for 15 minutes, spread on microscopic slides, fixed in 3:1 methanolacetic acid, and air dried. A G-banding technique was used for analysis.[20]

Analyses of immunoglobulin, T cell β-receptor, and bcr genes. High-mol wt DNA was extracted from the cells according to the method of Perucho et al[21] with minor modifications.[22] Ten to 20 μg of DNA were digested to completion with either *Eco*RI, *Bam*HI, *Hind*III, or *Bgl*II, electrophoresed through 0.75% agarose gels and transferred to nitrocellulose membranes.[23] The membranes were hybridized with nick-translated DNA probes as described previously,[22] washed five times with a solution containing 0.5 × SSC (45 mmol/L sodium chloride plus 4.5 mmol/L sodium citrate) and 0.1% (wt/vol) SDS at 65 °C and autoradiographed at −80 °C with an intensifying screen for several days. J$_H$ probe was a 3.3-kb *Eco*RI-*Hind*III fragment of (Ch4AHIgμ24),[24] and J$_\kappa$ probe was a *Sac*I-*Sac*I fragment of embryonic J$_\kappa$ region,[25] both obtained by the courtesy of Dr T. Honjo.

A plasmid (JUR-β2) containing human Tβ cDNA (JUR-β 2), which spanned from nine bases 5′ of J segment to poly-A tract,[26] was kindly provided by Dr T. W. Mak, and its 0.85-kb *Pst*I fragment was used as Tβ probe. A human *bcr* probe (Probe-1), a 1.2-kb *Hind*III-*Bgl*II fragment,[10] was purchased from Oncogene Science, Mineola, NY.

Analyses of c-abl genes' expression. RNA was extracted by the guanidinum, thiocyanate-cesium chloride method[27] and selected for poly(A)-containing species on an oligo(dT)-cellulose column.[28] Northern blot analysis of polyadenylated RNA extracted from the cells was carried out according to the method of Goldberg.[29] Ten micrograms of polyadenylated RNA in a solution containing 50% formamide; 7% formaldehyde; 20 mmol/L Mops, pH 7.0; 5 mmol/L Na acetate; and 1 mmol/L EDTA were heated to 60 °C for five minutes and cooled immediately on ice. The samples were electrophoresed through a 1.0% agarose gel containing 7% formaldehyde. Then the gel was equilibrated in 20× SSC for 45 minutes and blotted onto Biodyne membrane (Pall, Glen Cove, NY). After

baking in a vacuum at 80 °C for two hours, the membrane was hybridized with 2 to 3 × 10^6 cpm/mL of a nick-translated *abl*-specific probe (1.5-kb *Bgl* II fragment of pAb3[30]) in a solution containing 50% formamide; 5× Denhardt's solution; 5× SSPE; 0.3% SDS; 250 μg/mL *Escherichia coli* DNA at 42 °C overnight; washed three times with 2× SSC, 0.1% SDS and two times with 0.1× SSC, 0.1% SDS; and then autoradiographed at −80 °C.

Cultured leukemic cell lines and fresh leukemic cells used for gene analyses. Two Ph^1-positive leukemic cell lines, K562[7] and NALM-1,[8] and a T cell leukemic cell line, Molt-4F,[31] were used as controls. Fresh leukemic cells of six patients with Ph^1-positive ALL and seven patients with Ph^1-positive CML were obtained from either peripheral blood, bone marrow, or spleen. The clinical profiles and the analysis of cell surface markers of Ph^1-positive ALL cases are summarized in Table 1.

RESULTS

Cultivation of primary leukemic cells and establishment of a cell line. A gradual proliferation of leukemic cells was observed within a few days of culture. One half to one third of the medium was changed weekly. After the fourth week the cells started to grow vigorously and were maintained in a continuous culture by serial cell transfers. This cell line, TOM-1, has been maintained for more than 100 generations.

Cytologic characteristics of TOM-1 cell line. May-Grünwald-Giemsa (MGG) staining showed that the TOM-1 cells were mostly round or ovoid and uniformly large (12 to 15 μm in diameter). Each cell contained an ovoid nucleus composed of fine chromatin with one or two nucleoli. The cytoplasm was remarkably basophilic and contained no granules (Fig 1A). These cells were similar to the original leukemic cells in the patient's bone marrow (Fig 1B). Cytochemical analyses of the TOM-1 cells and the original leukemic cells showed that both cells were positive for PAS stain but negative for peroxidase, SBB, acid phosphatase, a-NBE, and NACE stains.

Phenotypical analysis. The results of surface marker analysis are shown in Table 2. The original leukemic cells were Ia-positive and CALLA-positive but lacked T cell markers and surface and cytoplasmic immunoglobulins. It

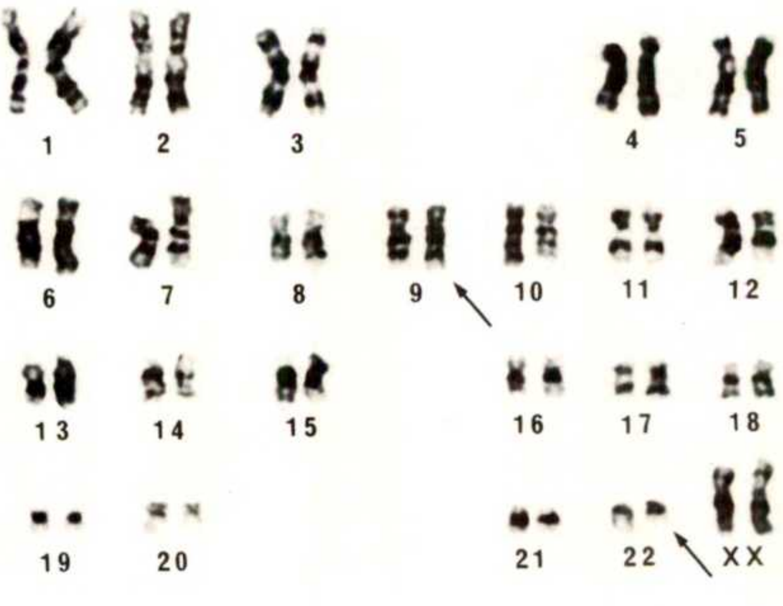

Fig 2. Chromosomal analysis of the TOM-1 cells. The Ph^1 chromosome, resulting from reciprocal translocation of chromosome 9 and 22 t(9:22), is indicated by arrows (→).

was not certain whether they were positive for the B1 antigen, because only 5% of the bone marrow aspirate cells were B1 antigen positive. Three months after the beginning of culture, the TOM-1 cells were 76% CALLA-positive, 99% OKIa1-positive, and 69% B1-positive. Thereafter they tended to lose CALLA-positivism, but the expression of B1 and Ia antigens remained unchanged. Neither surface Ig nor cytoplasmic Ig was detected. TdT activity was positive, and EBNA was negative.

Chromosomal analysis. Repeated karyotype analyses have revealed that all TOM-1 cells had the Ph^1 chromosome. Most cells showed the karyotype 46, XX, t(9:22) (Fig 2), but a few cells showed aneuploid karyotypes (47 to 49). These chromosomal and phenotypical analyses support the derivation of TOM-1 cells from the original leukemic cells.

Immunoglobulin gene configurations. Southern hybridization of *Eco*RI-digested DNA with J_H probe (3.4-kb *Eco*-RI-*Bam*HI fragment) is shown in Fig 3B. The TOM-1 cells contained rearranged J_H genes (lane 1). Southern hybridization of *Eco*RI-digested DNA with J_K probe showed that the TOM-1 cells contained only germ-line J_K genes (Fig 3C).

The leukemic cells from five patients with Ph^1-positive ALL were analyzed for their phenotypic profiles and Ig gene

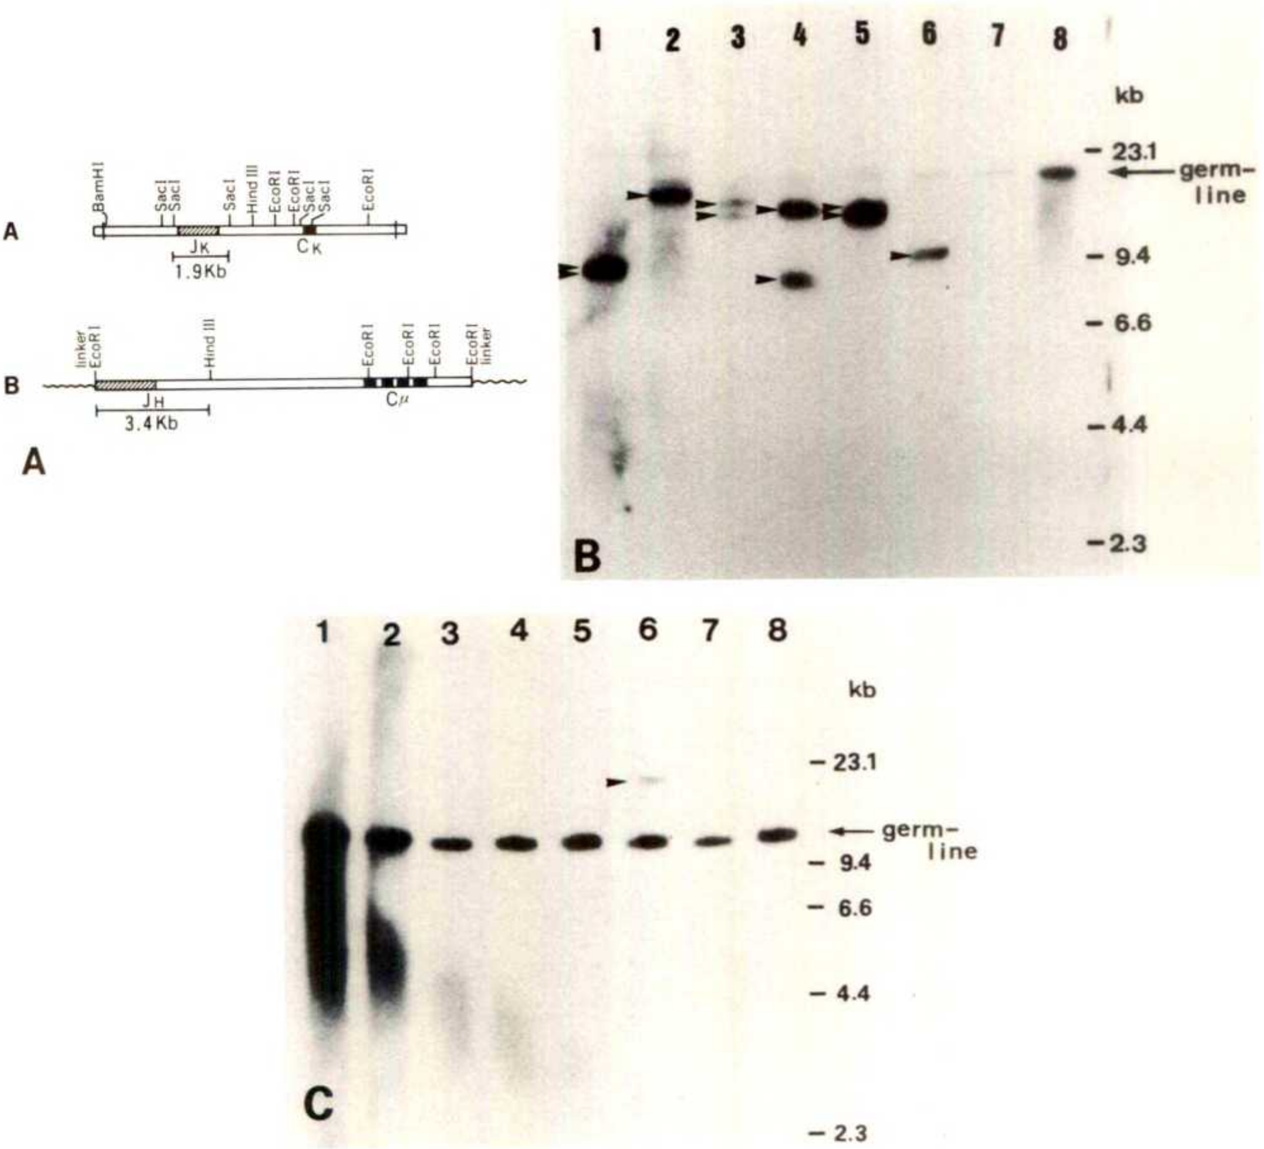

Fig 3. Analysis of immunoglobulin gene configurations by Southern blot hybridization. (A) The human Ig gene probes used in this study. A: restriction map of J_κ probe, a 1.9-kb *SacI-SacI* fragment was used as J_κ probe. B: restriction map of p(Ch4AH Igμ24). 3.4-kb *Eco*-RI-*Hind*III fragment subcloned in pBR 322 was kindly supplied by Dr T. Honjo. The 3.4-kb fragment was purified and used as J_H probe. (B) Configuration of J_H genes in *Eco*RI-digested DNA. (C) Configuration of J_κ genes in *Eco*-RI-digested DNA. The rearranged genes are indicated by arrows (▶). The TOM-1 cells (lane 1) and all five cases of Ph^1-positive ALL (lanes 2 through 6) showed rearranged J_H genes. The Molt-4F, a T cell leukemia cell line (lane 7), showed germ-line J_H gene (or an allele could have been deleted). A case of Ph^1-positive ALL (lane 6) contained a rearranged J_κ gene in *Eco*RI-digested RNA. Human placenta DNA is in lane 8.

rearrangements. The leukemic cells from all cases were Ia$^+$, CALLA$^+$, Pan-B$^{+/-}$, cIg$^-$, sIg$^-$, and T cell markers$^-$. These characteristics are common to CALLA-positive non-T, non-B ALL. All leukemic cells contained rearranged J_H genes (Fig 3B). Four of five cases showed germ-line J_K genes, but one case contained rearranged J_K genes in *Eco*-RI-digested DNA (Fig 3C, lane 6).

T cell β-receptor gene configurations. The Tβ cDNA probe used was JUR-β 2, which hybridizes with Cβ1 and Cβ2 because these two gene segments share a high degree of homology. *Eco*RI-digested germ-line Tβ region genes gave two hybridization signals, 11 kb for Cβ1 and 4 kb for Cβ2 (Fig 4A).[28] *Hind*III-digested germ-line Tβ region genes gave three hybridization bands, 8kb and 6 kb for Cβ2 and 3 kb for Cβ1 (Fig 4B). The TOM-1 cells contained only germ-line Tβ genes (lane 1). In five Ph^1-positive ALL cases, three cases contained germ-line patterns, but two other cases contained rearranged Tβ genes. (They showed deleted Cβ1 genes in both *Eco*RI-digested DNA and *Hind*III-digested DNA and rearranged Cβ2 genes in *Hind*III-digested DNA [lanes 3 and 4]). The results of Ig and Tβ gene analyses are summarized in Table 3.

Analysis of bcr gene rearrangements. We investigated *bcr* gene rearrangements in the TOM-1 cells and Ph^1-positive ALL cells (Fig 5). The TOM-1 cells and the K562 cells contained the rearranged *bcr* gene, although it was not detected in the NALM-1 cells. In three of 6 cases of Ph^1-positive ALL, the breakpoints were within *bcr* (lanes 4, 6, and 9). Case 5 showed the breakpoint near but not within *bcr* because rearrangement was found only in *Eco*RI-digested DNA (lane 8). Two cases showed germ-line pattern (case 2, lane 5; case 4, lane 7). In Ph^1-positive CML cases, all seven cases showed rearrangements within or near *bcr* (only one case was shown in Fig 5) (Table 4). A patient with refractory anemia with an excess of blasts (RAEB) in "transformation" who showed the hematologic findings simi-

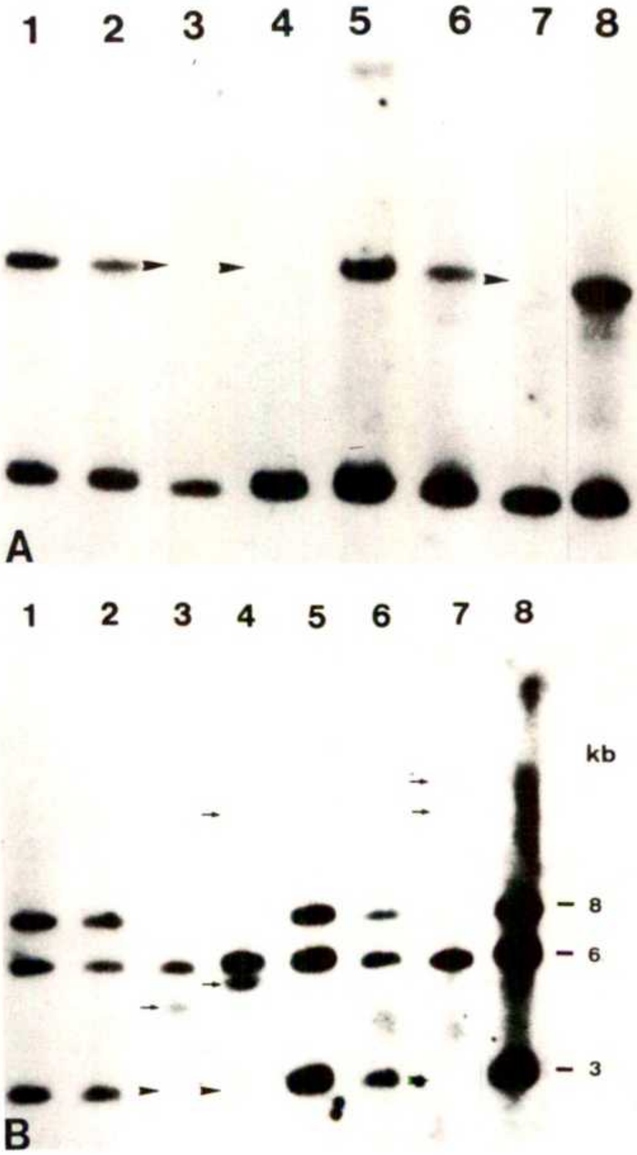

Fig 4. T cell β-receptor gene configurations. (A) Rearrangement patterns of TCβ genes in *Eco*RI-digested DNA and (B) in *Hind*III-digested DNA. Deleted or rearranged genes are indicated by marks (▶) or arrows (→), respectively. The TOM-1 cells and human placenta DNA contain germ-line Cβ genes (lanes 1 and 8, respectively). Those of the leukemic cells from five cases of Ph^1-positive ALL are shown in lanes 2 through 6. Case 2 (lane 3) and case 3 (lane 4) show rearranged Cβ 2 genes.

lar to those of Ph^1-negative CML (lane 11) and human placenta DNA (lane 12) showed germ-line patterns. These results are summarized in Table 4.

c-abl Gene expression. Amplification of c-*abl* gene in the TOM-1 cells and Ph^1-positive ALL cells was not detected by Southern blot analysis (data not shown). Northern blot analysis of polyadenylated RNA showed that the TOM-1 cells contained *abl*-related mRNA of only normal length, approximately 6-kb and 4-kb bands, without 8 kb transcript. On the other hand, the leukemic cells isolated from a patient with CML in myeloid crisis contained a novel 8-kb *abl*-related mRNA in addition to transcripts of normal length (Fig 6).

DISCUSSION

The Ph^1 chromosome, resulting from reciprocal translocations between chromosomes 9 and 22, t(9:22), is a cytogenetic abnormality found in more than 90% of CML patients.[1] Ph^1-positive leukemia cells have also been found in patients without history of chronic CML. Some of them show the features of acute myelogenous leukemias, but others clearly show those of ALL. Two series of investigations suggested an incidence of about 25% Ph^1-positivism among adult ALL cases,[2,3] and thus Ph^1-positive leukemia cells are not rare among adult ALL. However, as reported by Beard et al,[32] a blastic crisis of CML could occur without a preceding chronic phase. Therefore it may be necessary to differentiate lymphoid crisis of CML from Ph^1-positive ALL.

The patient presented herein, from whose bone marrow the TOM-1 cell line was derived, showed features of Ph^1-positive ALL. The Ph^1 chromosome was identified in the bone marrow cells on admission but disappeared from both bone marrow and peripheral blood cells once complete remission was achieved. Chromosomal analysis also showed no additional abnormality except for the presence of the Ph^1 chromosome, which is frequently found in blastic crisis of CML. Furthermore, a conversion into chronic CML was not seen. As these results support that the Ph^1 chromosome existed in the lymphoid cells but not in the hematopoietic stem cells, the diagnosis of Ph^1-positive ALL was appropriate.

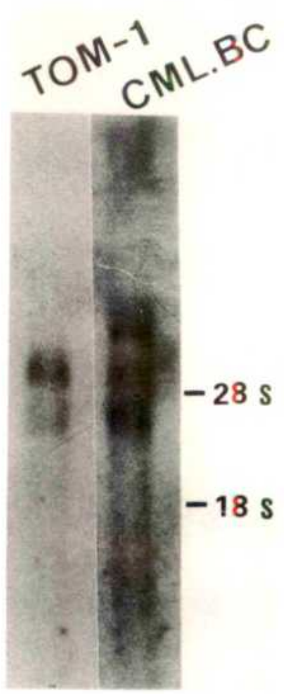

Fig 6. *abl*-Related mRNA expression. Northern blot analysis of polyadenylated RNA showed the TOM-1 cells contained *abl*-related mRNA of normal length, 6 kb and 4 kb bands; nevertheless, a case of CML in myeloid crisis (CML.BC) contained 8-kb *abl*-related mRNA in addition to transcripts of normal sizes.

The TOM-1 cells derived from this patient were positive for Ia and B1 antigens and were negative for surface and cytoplasmic Ig, CALLA, and T cell markers. Korsmeyer et al found that Ig gene rearrangements occurred in non-T, non-B (no cytoplasmic Ig)-cell ALL and concluded that most leukemic cells of non-T, non-B ALL resided as the progenitor of pre-B along the B cell pathway where they initiated J_H gene rearrangement, bore surface HLA-DR antigens, and later acquired CALLA and BA-1 antigens.[33] The TOM-1 cells contained rearranged IgH chain genes but retained germ-line κ chain and germ-line Tβ genes. These findings indicate that the TOM-1 cells reside at the progenitor level of pre-B cells.

Molecular events accompanied by the t(9:22) translocation have been extensively analyzed for Ph^1-positive CML, especially K562 cell line.[8,9] A novel 8-kb c-*abl*-related mRNA specific to CML is a fused transcript of two genes, the breakpoint cluster region gene on chromosome 22 and the c-*abl* gene translocated from chromosome 9 to 22.[34] The fused protein would unmask protein kinase activity of c-*abl* protein and may be important in the leukemic process of CML.[35] Recently Rodenhuis et al described that Ph^1 chromosome of childhood ALL does not involve *bcr*, in sharp contrast to Ph^1-positive CML.[36] In the present study we found that all seven cases of CML had a breakpoint within or near *bcr*, that TOM-1 cells also showed the breakpoint within *bcr*, and that four of six adult Ph^1-positive ALL cases contained rearranged *bcr* genes. We suggest the possibility that the breakpoints on chromosome 22 of adult Ph^1-positive

ALL might be different from those of childhood Ph^1-positive ALL.

By Southern blot analysis c-*abl* gene amplification in the TOM-1 cells and in the leukemic cells of Ph^1-positive ALL patients were not found. Northern blot analysis showed that 8-kb c-*abl*-related mRNA, in addition to the normal transcripts (6 kb and 4 kb), was found in the leukemic cells of Ph^1-positive CML in a myeloid crisis patient. On the other hand, the TOM-1 cells contained c-*abl* gene transcripts of only normal length, despite the fact that they showed the *bcr* gene rearrangement. At present, whether the observed c-*abl* gene expression in the TOM-1 cells is the representative of Ph^1-positive ALL accompanied by the *bcr* gene rearrangements remains to be determined; nevertheless, this finding suggests the possibility that the genetic mechanism in Ph^1-positive ALL might be different from that reported for CML. The newly developed TOM-1 cell line may be beneficial to this line of investigation.

ACKNOWLEDGMENT

We are grateful to Dr T. Honjo (Kyoto University) for providing the J_H and J_κ probes, to Dr Tak W. Mak (Ontario Cancer Institute) for providing the $T\beta$ gene probe, and to K. Yamaguchi and C. Oshiba for skillful technical assistance.

Impaired Nicotinamide Adenine Dinucleotide Synthesis in Pyruvate Kinase-Deficient Human Erythrocytes: A Mechanism for Decreased Total NAD Content and a Possible Secondary Cause of Hemolysis

By Charles R. Zerez and Kouichi R. Tanaka

Erythrocytes from individuals with pyruvate kinase (PK) deficiency have approximately half the total (oxidized and reduced) nicotinamide adenine dinucleotide (NAD) of normal erythrocytes. In order to elucidate the mechanism(s) for the decrease in total NAD, we examined NAD synthesis in intact erythrocytes. It is demonstrated that NAD synthesis is impaired in PK-deficient erythrocytes to a degree that is dependent on the PK activity and adenosine 5′-triphosphate (ATP) concentration of these cells. After incubation in the presence of fluoride, which simulates the characteristics of PK deficiency by inhibiting enolase, normal erythrocytes had impaired NAD synthesis and decreased ATP concentrations. Fluoride did not inhibit NAD synthesis in a hemolysate system that is not dependent on glycolysis for ATP generation. These data suggest that fluoride does not inhibit the enzymes of NAD synthesis and that impairment of NAD synthesis by fluoride is mediated by decreased ATP formation. Thus, it is concluded that impaired NAD synthesis in PK-deficient erythrocytes is caused by decreased ATP formation due to the PK deficiency. Since the rate of glycolysis is limited by the availability of NAD$^+$, it is suggested that impaired NAD synthesis causes further ATP depletion and thereby may enhance hemolysis in PK-deficient erythrocytes.

© 1987 by Grune & Stratton, Inc.

ERYTHROCYTES from pyruvate kinase (PK)-deficient individuals are characterized by several metabolic abnormalities.[1] One abnormality that remains unexplained is the decreased concentration of total (oxidized and reduced) nicotinamide adenine dinucleotide (NAD) in these cells.[2,3] Since the total NAD concentration in normal erythrocytes is approximately 40 μmol/L[4] and the K_m for NAD$^+$ of glyceraldehyde-3-phosphate dehydrogenase (G3PD) under physiological conditions is 143 μmol/L,[5] the rate of the G3PD reaction in vivo is limited by the concentration of NAD$^+$. Therefore, PK-deficient erythrocytes, with approximately half the total NAD of normal erythrocytes,[2,3] should have a lower in vivo G3PD reaction rate than normal erythrocytes. This is significant because, at steady state, a decreased rate of flux through G3PD will also cause a decreased rate of flux through the glycolytic reactions that follow the G3PD reaction. This includes both the phosphoglycerate kinase reaction, immediately following the G3PD reaction, and the PK reaction, which are the only adenosine 5′-triphosphate (ATP)-generating reactions in mature erythrocytes. Thus, decreased flux through the glycolytic reactions following the G3PD reaction will result in decreased ATP regeneration, which may enhance the hemolytic process in PK-deficient erythrocytes.

The decrease in the total NAD concentration in PK-deficient erythrocytes cannot be attributed to a decreased rate of flux through lactate dehydrogenase since the concentrations of both the oxidized and reduced forms of NAD are decreased. Thus, a decreased total NAD concentration must be due to other metabolic processes such as changes in the rate of synthesis or degradation of this coenzyme. It is not clear how intraerythrocytic NAD is degraded in humans since the only known enzyme capable of NAD degradation, NAD glycohydrolase (NADase; EC 3.2.2.6), is known to be located on the exterior of the erythrocyte membrane with no access to intraerythrocytic NAD.[6,7] NADase has also been shown to be an extracellular membrane-bound enzyme in other mammalian erythrocytes.[8,9] Therefore, to determine the mechanism responsible for the decrease in the total NAD concentration in PK-deficient erythrocytes, we have concentrated our efforts on an examination of the capacity of these cells to synthesize NAD. Human erythrocytes are capable of NAD synthesis from nicotinic acid (niacin) in a three-reaction pathway first elucidated by Preiss and Handler[10,11] (Fig 1). NAD biosynthesis is highly dependent on the availability of ATP: in addition to the ATP required for NAD biosynthesis from nicotinic acid and 5-phosphoribosyl-1-pyrophosphate (PRPP) (Fig 1), ATP is also required for the synthesis of PRPP from ribose-5-phosphate.[12] The data presented in this paper suggest that the decrease in the total NAD concentration in PK-deficient erythrocytes is due to impaired NAD synthesis caused by decreased ATP regeneration.

MATERIALS AND METHODS

Materials

D-Glucose was purchased from J.T. Baker Chemical Co, Phillipsburg, NJ. All other reagents were purchased from Sigma Chemical Co, St Louis. The potassium salt of fluoride was used throughout this investigation.

Methods

Isolation of erythrocytes. After obtaining informed consent, blood was obtained by routine venipuncture from PK-deficient

AMP, adenosine 5′-monophosphate; PP$_i$, inorganic pyrophosphate.

individuals and anticoagulated with heparin (15 U/mL whole blood). Blood from normal subjects and from individuals with hemolytic anemia of unknown etiology served as appropriate controls. The separation and washing of erythrocytes have been described previously.[13] Erythrocytes were used immediately after isolation.

Preparation of hemolysates. Hemolysates used to determine PK activity were prepared by using a freeze-thaw method.[13] Hemolysates used to measure NAD synthesis were prepared by using osmotic lysis of intact cells without freeze-thawing since the latter manipulation markedly decreases the conversion of nicotinic acid to the NAD precursor nicotinic acid mononucleotide[14] (Fig 1, reaction a). Suspensions of erythrocytes were centrifuged at 3,000 g for ten minutes. Two volumes of a solution containing 2.7 mmol/L EDTA, pH 7.0, and 0.70 mmol/L 2-mercaptoethanol were added to the packed erythrocytes and mixed gently. Examination under a light microscope revealed that more than 99.9% of the erythrocytes were lysed after this treatment. This hemolysate was used immediately in the NAD synthesis assay.

NAD synthesis assay. Conditions for the NAD synthesis assay in intact erythrocytes were a modification of the system of Preiss and Handler.[10] The incubation mixture contained 40 μmol potassium phosphate, pH 7.4; 75 μmol KCl; 75 μmol NaCl; 30 μmol D-glucose; 1.0 μmol nicotinic acid; 5.0 μmol L-glutamine; and intact erythrocytes equivalent to 42 mg hemoglobin (Hb) in a total volume of 1.00 mL. The assay was started by adding the appropriate volume of erythrocyte suspension, and the complete incubation mixture was maintained at 37°C. Conditions for the NAD synthesis assay in hemolysate were developed by modifying the previous incubation mixture. Glucose and inorganic phosphate were replaced with PRPP so that NAD synthesis would be independent of glycolysis. NaCl was eliminated since the maintenance of isotonic conditions was no longer necessary, and $MgCl_2$ was added since the endogenous concentration of magnesium is, presumably, decreased after cell lysis due to dilution of the cell contents. Thus, the incubation mixture for NAD synthesis in hemolysate contained 10 μmol Tris-HCl, pH 7.4; 5.0 μmol KCl; 1.0 μmol nicotinic acid; 15 μmol $MgCl_2$; 5.0 μmol PRPP; 5.0 μmol ATP; 5.0 μmol L-glutamine; and hemolysate equivalent to 42 mg Hb in a total volume of 1.00 mL. The assay was started by adding the appropriate volume of hemolysate, and the complete incubation mixture was maintained at 37°C.

NAD synthesis in both the intact erythrocyte and hemolysate incubation mixtures was determined by measuring the accumulation of the total (oxidized and reduced) NAD concentration after various times of incubation. Thus, at the times indicated, a 0.20-mL aliquot was withdrawn, maintained in a boiling water bath for 60 seconds, and then cooled to 0°C. The heat-treated aliquot was centrifuged to remove cell debris and denatured proteins. To minimize interference by compounds present in the incubation mixture, the supernatant was diluted tenfold before determination of the total NAD concentration with the sensitive cycling method of Bernofsky and Swan.[15] The total NAD concentration, instead of oxidized NAD (NAD$^+$), was measured since NAD$^+$ can readily be converted to its reduced form (NADH) following synthesis.

ATP formation from PRPP. Conditions for ATP formation from PRPP and endogenous AMP and inorganic phosphate were identical to those used to measure NAD synthesis in the hemolysate

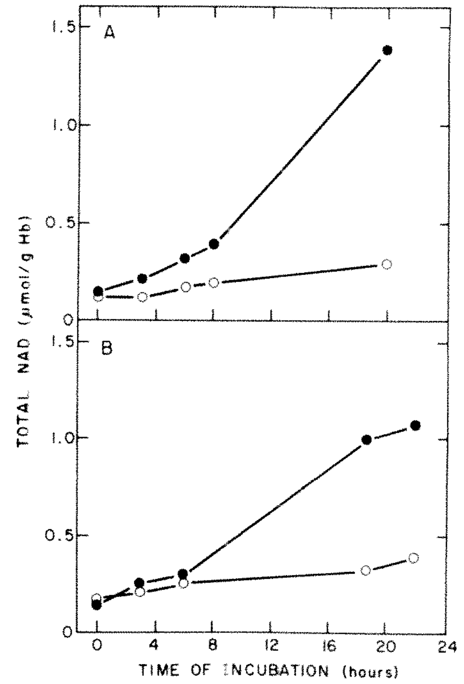

Fig 2. NAD synthesis in intact normal erythrocytes. (A) Optimal conditions were used (see Materials and Methods). (B) Physiological conditions were used (5.0 mmol/L glucose, 1.0 mmol/L glutamine, and 5.0 mmol/L inorganic phosphate; other conditions are the same as for the optimal system). The following incubation conditions were used: complete system (closed circles), without glutamine (open circles).

Table 1. The Quantity of NAD Synthesized in Intact Red Cells From Normal Subjects and PK-Deficient Patients After 20 Hours of Incubation

Subject	Splenectomy	PK Activity (μmol/min · mL RBC)	ATP (μmol/g Hb)	Total NAD Accumulated (μmol/g Hb)
Normal (n = 8)	No	5.53 ± 0.82	3.61 ± 0.66	1.35 ± 0.24
PK deficient				
Patient 1 (41% reticulocytes)	Yes	0.60	1.90	0.53
Patient 2 (7.5% reticulocytes)	No	0.57	2.54	0.70
Patient 3 (7.5% reticulocytes)	No	1.52	2.83	1.04

system (see earlier) except that ATP was omitted from the reaction mixture. When ATP formation from PRPP was measured in the presence of exogenous AMP and inorganic phosphate, the aforementioned reaction mixture was supplemented with 1.0 mmol/L AMP and 20 mmol/L potassium phosphate (pH 7.4). At the indicated times, aliquots were withdrawn and heat-treated as described earlier. Following centrifugation, the supernatant was used to quantitate ATP as described by Beutler.[16]

The rate of ATP formation was also measured by using a continuous spectrophotometric assay that contained 10 μmol Tris-HCl, pH 7.4; 5.0 μmol KCl; 1.0 μmol nicotinic acid; 15 μmol $MgCl_2$; 5.0 μmol PRPP; 5.0 μmol L-glutamine; 0.40 μmol NADP; 1.0 μmol D-glucose; 1.2 IU glucose-6-phosphate dehydrogenase; 8.0 IU hexokinase; and hemolysate equivalent to 1.7 mg Hb in a total volume of 1.00 mL. The reaction mixture was preincubated at 37°C and then started by adding the appropriate volume of PRPP. The absorbance was monitored at a wavelength of 340 nm by using a Gilford model 252 spectrophotometer (Gilford, Ciba-Corning Diagnostics, Oberlin, OH) with a slit width of 0.80 mm. The relatively wide slit width was required because the amount of hemolysate necessary for the reaction resulted in a relatively high initial absorbance. However, because the absorbance band of NADPH is fairly wide, the millimolar extinction coefficient of NADPH remains 6.22 at a slit width of up to 1.0 mm.[16]

Other methods. PK activity was determined as described by Tanaka.[17] The whole blood ATP content was determined spectrophotometrically[18] by using neutralized perchloric acid extracts.[16] This method was also used to measure the ATP concentration in intact erythrocytes during incubation with fluoride. The Hb concentration was determined by using the cyanmethemoglobin method.[16] Data were expressed as the mean ± 1 SD.

RESULTS

Intact human erythrocytes are capable of NAD synthesis when incubated in the presence of glucose, inorganic phosphate, glutamine, and nicotinic acid.[10,19] We have found that normal erythrocytes increased their original total NAD content five to 15 times after incubation with the latter compounds for 20 hours (Fig 2A). Relatively little total NAD was accumulated in the absence of glutamine from the incubation mixture (Fig 2A). Since glutamine is essential for NAD synthesis in human erythrocytes,[11] this suggests that the total NAD accumulation is due to NAD synthesis. To a lesser extent, the total NAD also accumulated when the concentrations of glucose, glutamine, and inorganic phosphate in the incubation mixture were reduced to simulate more physiological conditions (Fig 2B). This suggests that NAD synthesis in normal mature RBC is physiologically significant.

The quantity of total NAD accumulated after 20 hours of incubation in erythrocytes from eight normal subjects was 1.35 ± 0.24 μmoL/g Hb (Table 1). RBC from five patients with hemolytic anemia of unknown etiology (9.0% to 15% reticulocytes) accumulated 1.14 ± 0.14 μmol NAD/g Hb. In contrast, erythrocytes from three PK-deficient patients accumulated substantially less total NAD than erythrocytes from normal subjects (Table 1). NAD synthesis in PK-deficient erythrocytes correlated positively with PK activity and the level of intraerythrocytic ATP. Erythrocytes from PK-deficient patient 3, who had the highest PK activity and ATP content, accumulated 1.04 μmol total NAD/g Hb (Table 1). In contrast, erythrocytes from PK-deficient patient 1, who had the lowest ATP content, accumulated only 0.53 μmol total NAD/g Hb (Table 1). Since this patient had undergone splenectomy (Table 1), presumably a greater proportion of more defective erythrocytes was in circulation.

Since the capacity of PK-deficient erythrocytes to synthesize NAD correlated with their ATP content, we examined the total NAD accumulation in normal erythrocytes using fluoride to inhibit enolase[20] and reduce ATP formation. Incubation of intact normal erythrocytes with fluoride under conditions that yield optimal NAD synthesis resulted in ATP depletion to a degree that was dependent on the concentration of fluoride added to the incubation mixture (Fig 3). Hence, as little as 0.1 mmol/L fluoride led to a 28% decrease in the ATP content after six hours of incubation (Fig 3). A fluoride concentration of 1.0 mmol/L was sufficient to cause a 34% decrease in the ATP concentration after only three hours of incubation (Fig 3). The addition of fluoride to the incubation mixture resulted in marked inhibition of NAD synthesis in normal intact erythrocytes. A fluoride concentration of only 0.10 mmol/L caused a 17% inhibition of total NAD accumulation (Fig 4). Higher concentrations of fluoride were more effective in impairing NAD synthesis, with 1.0 mmol/L fluoride causing full inhibition of total NAD accumulation (Fig 4).

The impairment of NAD synthesis by fluoride is most likely due to decreased ATP regeneration. However, since it is not known what effect fluoride has on the enzymes of NAD synthesis, we determined the effect of fluoride on these enzymes by measuring total NAD accumulation in a hemolysate system that is not dependent on glycolysis (and enolase).

Since the present experiment is the first known demonstration of NAD synthesis in a human hemolysate system, the

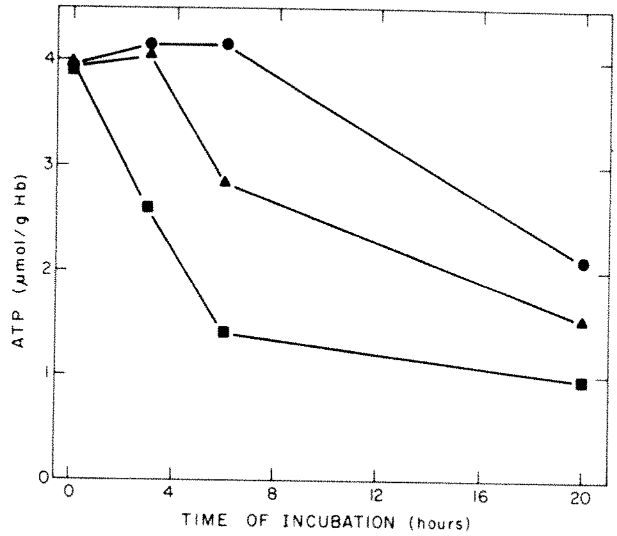

Fig 3. The effect of fluoride on the ATP concentration of intact normal erythrocytes under optimal conditions for NAD synthesis. The following incubation conditions were used: complete system (circles), with 0.10 mmol/L fluoride (triangles), with 1.0 mmol/L fluoride (squares).

Table 2. The Effect of Omissions of Various Components of the Incubation Mixture on NAD Synthesis in Hemolysate

Contents of Incubation Mixture	Total NAD Accumulated in 20 Hours (μmol/g Hb)
Complete	0.361
Without nicotinic acid	0
Without $MgCl_2$	0
Without glutamine	0
Without PRPP	0
Without ATP	0.247
Without ATP and PRPP	0

effect of omissions of various components of the incubation mixture was examined. There was no total NAD accumulation in the absence of nicotinic acid, $MgCl_2$, glutamine, or PRPP after 20 hours of incubation (Table 2). In contrast, the absence of ATP resulted only in a 32% decrease in the total NAD accumulation after 20 hours of incubation (Table 2). However, there was no total NAD accumulation when both ATP and PRPP were excluded from the incubation mixture (Table 2). This suggests that the substantial accumulation of total NAD observed in the absence of added ATP may be due to ATP regeneration from PRPP and endogenous AMP. Previous studies have shown that PRPP synthetase (EC 2.7.6.1), the enzyme responsible for PRPP synthesis from ATP and ribose-5-phosphate, can catalyze the reverse reaction nearly as well as the forward reaction.[21] To determine whether ATP was being regenerated from PRPP under our experimental conditions, we measured ATP formation under the same conditions that yield optimal NAD synthesis in our hemolysate system. To ensure that the presence of the NAD precursors does not interfere with the reverse PRPP synthetase reaction, we first examined ATP formation from PRPP when AMP and inorganic phosphate were exogenously supplied to the reaction mixture. The results indicate that ATP accumulated in a time-dependent manner in the presence of PRPP (Fig 5A). No ATP was found to accumulate when PRPP was absent from the reaction mixture (Fig 5A). This suggests that the NAD precursors present in the reaction mixture do not interfere with ATP formation from PRPP.

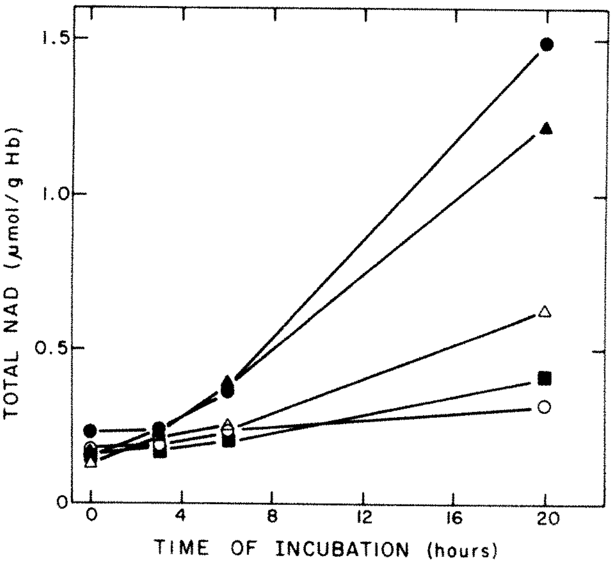

Fig 4. The effect of fluoride on NAD synthesis in intact normal erythrocytes under optimal conditions. The following incubation conditions were used: complete system (closed circles), without glutamine (open circles), with 0.10 mmol/L fluoride (closed triangles), with 0.50 mmol/L fluoride (open triangles), with 1.0 mmol/L fluoride (squares).

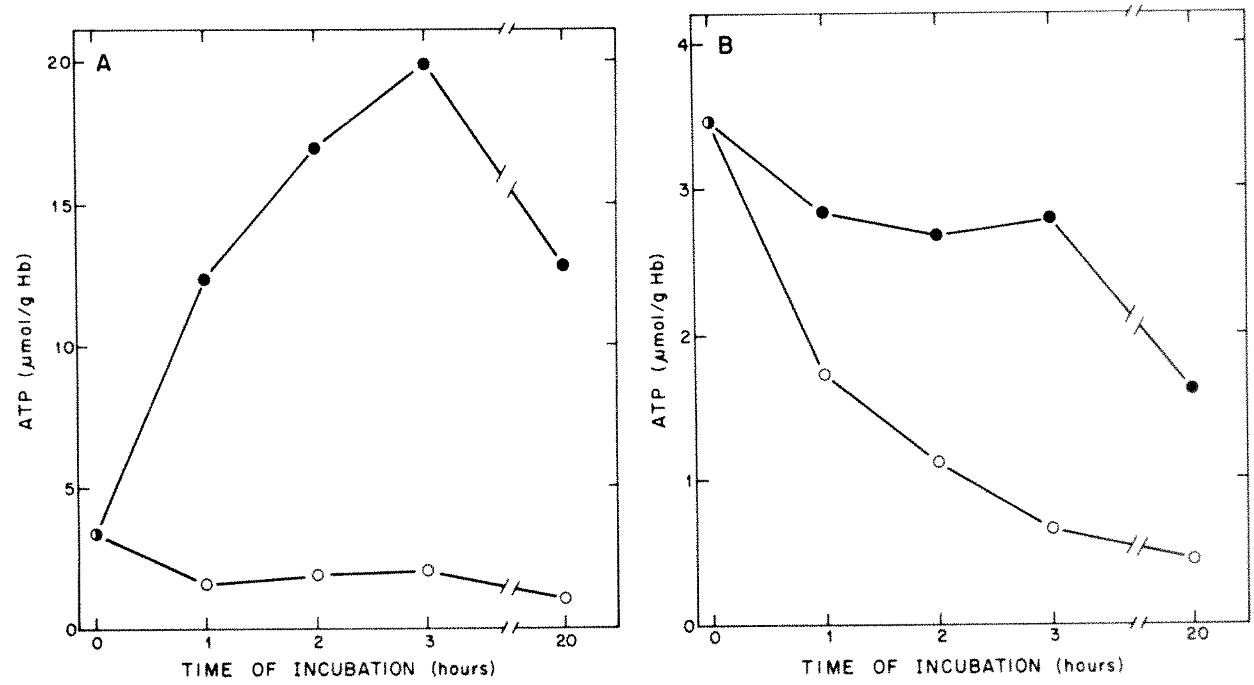
Subsequently, we examined ATP formation from PRPP using the hemolysate's endogenous AMP and inorganic phosphate. Under these conditions, no accumulation of ATP was observed in the presence of PRPP (Fig 5B). However, in the absence of PRPP, the ATP content decreased rapidly (Fig 5B). The lack of ATP accumulation in this system suggested that the rate of ATP formation from PRPP and endogenous AMP and inorganic phosphate was not rapid enough to overcome the rate of ATP utilization. To confirm this hypothesis, we devised a continuous spectrophotometric system in which the formation of ATP results in the production of NADPH and a concomitant increase in the absorbance at 340 nm. In this system, the ATP that is formed is "trapped" by the detection system before it can be utilized for NAD synthesis and/or other processes. Under these conditions, ATP was formed readily from endogenous AMP and inorganic phosphate in the presence of PRPP and hemolysate (Fig 5C). It is noteworthy that a significant rate of ATP formation (4.6 μmol/h · g Hb at steady state) was obtained with only 1/25th the hemolysate (1.7 mg Hb) used for the NAD synthesis assay (Fig 5C). No significant ATP formation was observed in the absence of either PRPP or hemolysate (Fig 5C). Furthermore, the addition of exogenous AMP and inorganic phosphate to this system yielded a more rapid rate of ATP formation (Fig 5C) that is consistent with the rapid ATP accumulation of Fig 5A. These data confirm that ATP is formed from PRPP and endogenous AMP and inorganic phosphate under optimal conditions for



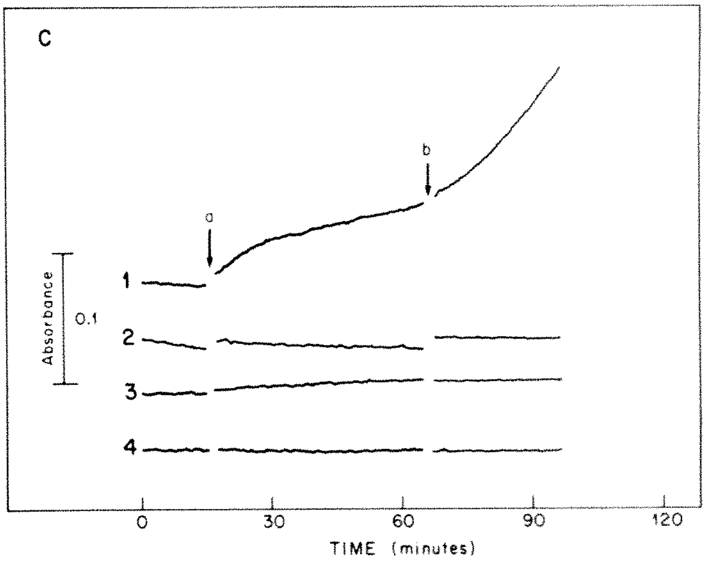


Fig 5. ATP formation from PRPP in hemolysate from normal erythrocytes. Conditions were identical to those used to measure NAD synthesis in hemolysate except that ATP was omitted. (A) Reaction mixtures contained exogenous AMP and inorganic phosphate (see Materials and Methods). (B) Reaction mixtures contained no exogenous AMP and inorganic phosphate. The following incubation conditions were used: complete system (closed circles), without PRPP (open circles). (C) ATP formation measured using a continuous spectrophotometric assay system (see Materials and Methods). The following incubation conditions were used: complete system (tracing 1), without PRPP (tracing 2), without hemolysate (tracing 3), without PRPP and hemolysate (tracing 4). The reactions were started (arrow a) by the addition of PRPP (tracings 1 and 3) or water (tracings 2 and 4). At the indicated time (arrow b), the reaction mixtures were supplemented with AMP and inorganic phosphate to a final concentration of 1.0 mmol/L and 20 mmol/L, respectively.

NAD synthesis in hemolysate. Thus, the substantial quantities of total NAD accumulated in the absence of ATP and in the presence of PRPP (Table 2) is due to the regeneration of ATP from PRPP.

In the hemolysate–NAD synthesis system, there was an initial decrease in the total NAD concentration within the first two hours of incubation (Fig 6). Subsequently, total NAD accumulated at a linear rate up to 20 hours of incubation (Fig 6). The addition of up to 1.0 mmol/L fluoride to the incubation mixture did not affect total NAD accumulation in the hemolysate system (Fig 6). The initial decrease in total NAD concentration that is observed in this system (Fig 6) may be caused by the exposure of the intraerythrocytic NAD pool to the extracellular membrane-bound NADase[6,7] after red cell lysis. The lack of a decrease in the total NAD content when intact erythrocytes are used (Figs 2A and 2B) is consistent with this hypothesis since intraerythrocytic NAD is not exposed to NADase under these conditions.

DISCUSSION

We have shown that intact PK-deficient erythrocytes have impaired NAD synthesis since they accumulated less total NAD than normal erythrocytes when incubated with precursors essential for NAD biosynthesis (Table 1). Impaired NAD synthesis in PK-deficient red cells is not due to the higher proportion of reticulocytes since high reticulocyte red cell samples without PK deficiency did not demonstrate significantly impaired NAD synthesis. The positive correlation between NAD synthesis, PK activity, and the level of

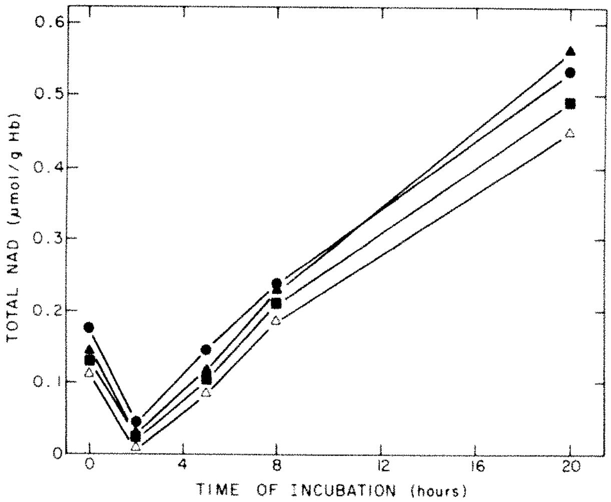

Fig 6. The effect of fluoride on NAD synthesis in hemolysate from normal erythrocytes. The following incubation conditions were used: complete system (closed circles), with 0.10 mmol/L fluoride (closed triangles), with 0.50 mmol/L fluoride (open triangles), with 1.0 mmol/L fluoride (squares).

intraerythrocytic ATP suggested that impaired NAD synthesis in PK-deficient erythrocytes may be caused by decreased ATP regeneration due to low PK activity. To provide further evidence for this hypothesis, we measured total NAD accumulation in normal erythrocytes in the presence of fluoride. This ion is an inhibitor of enolase[20] and has been used previously to simulate the characteristics of PK deficiency.[22] The decrease in the ATP concentration with time at all fluoride concentrations used (Fig 3) suggests that fluoride was inhibiting enolase (and glycolysis) and, presumably, simulating PK deficiency under the conditions used.

We have found that fluoride is a potent inhibitor of NAD synthesis in intact erythrocytes (Fig 4) even at concentrations that cause only partial depletion of ATP (Fig 3). The sensitivity of NAD synthesis to inhibition by fluoride may be due to the requirement of several ATP molecules for the synthesis of one NAD molecule (Fig 1). The inhibition of NAD synthesis in intact erythrocytes by fluoride cannot be due to inhibition of PRPP synthetase since fluoride concentrations as high as 50 mmol/L do not affect PRPP synthetase activity in crude hemolysate.[23] To determine whether fluoride interfered with the activity of the enzymes of NAD biosynthesis, we measured the total NAD accumulation in hemolysate by substituting PRPP for glucose and inorganic phosphate. Under these conditions, NAD synthesis will not be dependent on glycolysis and hence enolase to provide ATP for PRPP formation. There was a substantial accumulation of total NAD in this hemolysate system (Table 2 and Fig 6). Since there was no accumulation of total NAD when components essential for NAD synthesis such as nicotinic acid, glutamine, $MgCl_2$, or PRPP were excluded (Table 2), it is suggested that the total NAD accumulation in the hemolysate system was due to NAD synthesis. The substantial accumulation of total NAD observed in the absence of added ATP is due to ATP regeneration from PRPP and endogenous AMP since no total NAD accumulation is observed in the absence of both ATP and PRPP (Table 2) and since ATP formation from PRPP and endogenous AMP can be readily demonstrated (Fig 5C). When NAD synthesis was measured in the hemolysate system and glycolysis and enolase were bypassed, fluoride had no significant effect on total NAD accumulation (Fig 6). This suggests that fluoride did not inhibit the enzymes of NAD biosynthesis in hemolysate.

The lack of inhibition of the NAD biosynthetic enzymes and PRPP synthetase by fluoride in hemolysate suggests that impairment of NAD synthesis in intact normal erythrocytes in the presence of fluoride is caused by decreased ATP formation. These data support the hypothesis that impaired NAD synthesis in intact PK-deficient erythrocytes is caused by decreased ATP regeneration due to the PK deficiency itself. Furthermore, our data suggest that impaired NAD synthesis is a primary cause of the decreased total NAD concentration in PK-deficient erythrocytes. Previous studies from this laboratory have shown that PK-deficient erythrocytes have decreased PRPP synthetase subunit aggregation and therefore a less active enzyme in vivo.[24] This is caused by the decreased ATP and increased 2,3-diphosphoglycerate concentrations in these erythrocytes.[24] Thus, we have suggested that impaired NAD synthesis may also be mediated by the decreased in vivo activity of PRPP synthetase.[24]

Impaired NAD synthesis in PK-deficient erythrocytes is significant because the rate of the G3PD reaction and hence glycolysis is limited by the NAD^+ content of the erythrocyte. Thus, impaired NAD synthesis may cause further ATP depletion and may be a secondary cause of hemolysis in PK-deficient erythrocytes.

On the Mechanisms of Sensitization and Attachment of Antibodies to RBC in Drug-Induced Immune Hemolytic Anemia

By A. Salama and C. Mueller-Eckhardt

The mechanisms of sensitization and attachment of drug-dependent antibodies to RBC in drug-induced immune hemolytic anemias are largely speculative. Nomifensine has been incriminated in causing immune hemolysis in a large number of patients. The hemolysis was usually of the so-called immune complex type, less commonly of the autoimmune type, and more surprisingly, few patients had developed both types of hemolysis. To determine whether nomifensine (metabolite)-dependent antibodies (ndab) exhibit specificity for antigenic structures of RBC membranes, 30 ndab were tested against large panels of RBC with common and rare antigens. We found that only 14 out of 30 ndab were invariably reactive with all cells tested. Nine antibodies were, similar to the majority of idiopathic or drug-induced autoantibodies, not or only weakly reactive with Rh_{null} RBC. Three antibodies did not react with cord RBC and could be inhibited by soluble I antigen. The remaining four antibodies gave inhomogeneous reaction patterns or were even negative with selected RBC; their specificity could not be identified. On a Scatchard plot analysis of one ndab, a maximum of 173,000 drug-dependent antibodies of the IgG class can specifically bind per RBC in the presence of the drug. Although nomifensine and its metabolites do not attach tightly onto RBC, our results clearly indicate that RBC do not act as "innocent bystanders," but rather serve as a surface for (1) a loose attachment of drugs that possibly cause a subtle structural change in the cell antigens and, by this means, allow in vivo sensitization; and (2) a specific binding of the resultant antibodies. This concept would explain why these antibodies can be directed against drug-cell complexes, against cell antigens alone (autoantibodies), or against both in the same patient.

© 1987 by Grune & Stratton, Inc.

NOMIFENSINE, an antidepressant drug, has been recently withdrawn because of the frequent occurrence of life-threatening immune-mediated intravascular hemolysis. In almost all cases this syndrome appeared to reflect the typical clinical and serological picture of the so-called immune complex-mediated immune hemolysis. The hemolysis was usually transitory, intravascular, and often associated with renal failure. In vitro studies have shown that the drug does not bind firmly to target cells and that the causative antibodies react with RBC only in the presence of the drug[1-4] and/or its metabolites, which leads to cell lysis by fixation of the terminal complement complexes.[5-7] The occurrence of autoimmune hemolytic anemia secondary to therapy with the drug has also been noted.[8,9]

A major, yet unresolved problem in this syndrome is the mechanism of sensitization and the true antigenic sites that determine the specificity of the resultant antibodies. The prevailing notion anticipates that drugs (haptens) first conjugate with some soluble noncellular macromolecule to give rise to the subsequent formation of high-affinity antibodies. These antibodies then combine with drugs to form antibody-drug complexes that may attach nonspecifically to RBC by an "innocent bystander" mechanism.[10] This hypothesis is based on the assumption that immunization does not require conjugation of the drug with RBC and that the antibodies produced do not have specificity for erythrocyte antigens.[10] We have recently identified in one patient with nomifensine-induced immune hemolysis multiple nomifensine (metabolites)-dependent antibodies (ndab) that recognize Rhesus blood group antigens.[11] In another report the presence of receptors on RBC for certain drugs or drug-antibody complexes has been suggested.[12] Therefore, we have reexamined a large number of ndab in order to see whether they exhibit specificity for known blood group antigens.

Our results show that 16 out of 30 antibodies do indeed have specificity that is not only controlled by the drug and/or its metabolites but also by defined RBC antigens, particularly of the Rhesus and I/i systems. These findings provide, we believe, supportive evidence that in some circumstances in vivo sensitization to drugs may be related to the formation of loose, but immunogenically effective drug-cell complexes.

MATERIALS AND METHODS

Antibodies. Serum samples of 30 patients with clinical and laboratory criteria consistent with the diagnosis of drug-induced immune hemolytic anemia (DIHA) of the so-called immune complex type were studied.[6,9] Each serum had ndab of the IgG and/or IgM classes invariably reactive with pooled normal RBC in the presence of ex vivo antigen[6,9] of the drug (urine containing the drug and its metabolites). Additionally, 22 eluates or sera containing RBC IgG autoantibodies (seven induced by nomifensine, four by α-methyldopa, one by cianidanol [(+)-2-(3,4-dihydroxyphenyl)-3,5,7-chromatriol], and ten unselected "idiopathic" autoantibodies) were concomitantly studied.

RBC. The following RBC were used: (1) pooled RBC freshly obtained from three or four healthy blood donors of group O with all major Rhesus factors, ie, D, C, c, E, e; (2) A_2 Rh_{null} RBC, kindly provided by Professor S. Seidl (Frankfurt, FRG); (3) two commercially available panels of O RBC (Ortho Pharmaceutical Corp, Raritan, NJ); (4) a panel of RBC lacking high-frequency antigens or having rare antigens (see the legend to Table 1) was kindly supplied by the Medical Research Council Blood Group Unit, London.

Drugs. The ex vivo antigen was urine of a volunteer collected 4.5 hours after the ingestion of 200 mg nomifensine. Purified nomifen-

sine was kindly provided by Hoechst Pharmaceuticals (Frankfurt, FRG).

Serological procedures. The reactivity of antibodies was tested as described.[6,9] Serum samples were titrated against the cells in the presence of urine before (control) and after drug ingestion (ex vivo antigen). If the sera were incompatible with the cells to be tested due to isoagglutinins (anti-A, B) samples were preabsorbed with pooled A_1 or B RBC. After incubation for two hours at 37°C, the reactions were read visually for agglutination. Thereafter the RBC were washed three times in saline and tested by the indirect antiglobulin test using polyvalent antiglobulin serum (Ortho).

Inhibition tests. Drug-dependent antibodies that showed reactivity against adult but not against cord RBC were reinvestigated with adult RBC in the presence of defatted and preheated human milk (ten minutes in boiling water) as described for anti-I.[13]

Absolute number of antibodies attached per RBC. Plasma containing a pure nomifensine-dependent IgG antibody (no. 1, a gift from Dr B. Habibi, Paris) was incubated with 10×10^6 RBC (in 0.02 mL saline) in the presence of nomifensine or saline (control). In preceding experiments the amount of plasma and drug needed for maximum binding of antibodies to RBC had been determined (0.1 mL of plasma and 0.05 mL of a solution of 0.1 g/dL [wt/vol] nomifensine dissolved in 0.15 mol/L saline methanol [1:10]). After incubation for two hours at 37°C the RBC were separated by centrifugation through 1 mL of calcium-free Tyrode buffer (0.13 mol/L NaCl, 27 mmol/L KCl, 16 mmol/L $NaHCO_3$, 0.36 mmol/L $Na_2H_2PO_4$, 5 mmol/L $MgCl_2$-$6H_2O$, pH 7.2) that was supplemented with 0.2% bovine serum albumin, 1% glucose,[14] and 0.001 g/dL nomifensine (final concentration) to maintain maximal binding of the antibodies onto the cells.[6] The cells were resuspended in 0.1 mL of saline containing the drug, transferred to fresh tubes, and reincubated with serial dilutions of radiolabeled[15] and chromatographically purified polyclonal $F(ab)_2$ antihuman IgG (Fc) antibodies (Jackson Immunoresearch Laboratories, Avondale, PA). After incubation (30 minutes at room temperature) the cells were centrifuged again through the same buffer, and the radioactivity of the RBC pellet was measured. Centrifugation through this buffer completely eliminates unbound molecules.[14] All experiments were run in triplicate, including the controls.

RESULTS

All antibodies reacted with pooled O RBC in the presence of ex vivo antigen (agglutination and/or positive indirect antiglobulin test), but in no case in the presence of urine before ingestion of the drug (negative control). Fourteen antibodies reacted with Rh_{null} RBC as well as with other rare or common RBC whether they were tested undiluted or diluted. In contrast, 16 antibodies showed inhomogeneous reaction patterns with the RBC tested, and the majority of them had specificity to defined RBC antigens (Table 1). Nine of these antibodies were not or only weakly reactive with Rh_{null} cells, and three antibodies (nos. 5, 22, 35) were negative with cord RBC. Against a panel of common RBC, some of the former antibodies, if they were available in sufficient amounts, also exhibited specificity to "simple" Rh antigens, ie, C, c, f, or to the I antigen (Table 1).

The I specificity was also confirmed by inhibition tests using soluble I antigen in human milk (Table 2). Although the remaining four antibodies (nos. 4, 17, 18, 30) seemed to recognize certain RBC antigens, their specificity could not be identified.

To study the binding characteristics of the antibodies with homogeneous reaction patterns, we analyzed the attachment of a representative antibody by Scatchard plot analysis. For this experiment, a pure IgG ndab[1] was chosen. If it is assumed that one molecule of the $F(ab)_2$ binds to one molecule of human IgG, the maximum amount of antibody binding sites was 173,000 per RBC (Fig 1). This value is, however, only an approximation since the antibodies used

were polyclonal and only one ndab was studied. The value(s) would be more precise if purified and radiolabeled $F(ab)_2$ fragments of ndab were used. Nevertheless, the straight-line extrapolation in Fig 1 would suggest that the antibody studied was of restricted heterogeneity. When the serum was incubated with the same cells in the absence of the drug (control), no binding of antibody was seen. Washing of the antibody-coated cells in the absence of drug removed at least 70% of cell-bound antibodies.

In comparison with ndab, ten unselected idiopathic and 12 drug-induced autoantibodies were tested against the same RBC. In all groups approximately 50% of the antibodies were not reactive with Rh_{null} cells (Table 3), thus indicating the absence of identical binding sites for all these antibodies.

DISCUSSION

Since the pioneer work of Landsteiner,[17] it has generally been accepted that haptens, usually substances of a molecular weight of less than 1,000 daltons, can acquire immunogenicity only after coupling to a macromolecular carrier. This compound antigen, ie, hapten-protein complex, will then display a multitude of antigenic sites that may provoke the production of various antibody populations with different specificities.[18-20]

Table 3. Reactivity of Idiopathic and Drug-Induced Autoantibodies Against Normal and Rh_{null} RBC

Autoantibodies (Total)	Induced by (Drug)	Not Reactive With Rh_{null}
7*	Nomifensine	4
4	α-Methyldopa	3
1†	Cianidanol	1
10	Idiopathic	5

All autoantibodies were eluates from autologous or homologous RBC.

*The autoantibodies in patients 48 and 50[9] are included. Both of them were, like the drug-dependent antibodies in the same patients, reactive with Rh_{null} cells.

†Not yet published.

Immune-mediated cytopenias are well-known hazards of drug therapy. However, the etiology of this disorder and the molecular basis of drug-antibody-cell interactions have remained largely speculative. Ackroyd[21] postulated that the drug acts as a hapten and the resultant antibodies bind to drug-coated cells, which leads to complement activation on the cell surface. This concept was called in question by the fact that most drugs involved in drug-induced cytopenias do not bind firmly to target cells.[10] An alternative model claimed that drugs form stable compounds with plasma macromolecules that react with antibody to form immune complexes that then attach nonspecifically onto the target cells.[22,23] But neither the mechanism proposed by Ackroyd nor the hypothesis of nonspecific attachment of drug-antibody complexes can satisfactorily explain the occurrence of drug-induced autoimmune hemolytic anemias, ie, by α-methyldopa.[24]

Of the three possible mechanisms of DIHA the so-called immune complex type is clinically and serologically by far the least understood form.[10] In our recent reports on a total of 51 patients with nomifensine-induced immune hemolysis,[5,6,9,11] the majority of patients (42 cases) appeared to belong in the category of the immune complex type as judged from clinical as well as serological findings, whereas five

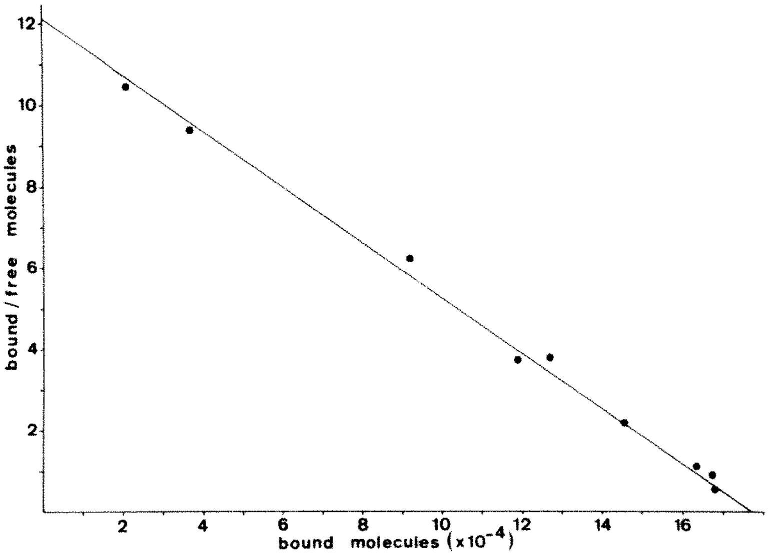

Fig 1. Absolute number of anti-IgG molecules bound per RBC preincubated with nomifensine-dependent antibody in the presence of the drug. The background radioactivity of RBC preincubated with the same serum in the absence of the drug was measured concomitantly (control). This background radioactivity (<0.01%) was subtracted from the total amount of cell-associated radioactivity for each dilution of radiolabeled antibody.

patients had developed a true autoimmune hemolytic anemia and three patients had both types of immune-mediated hemolysis. Thus, the most convincing way to address the question whether or not the RBC act as a carrier surface for the drug and its metabolites would be to demonstrate specificity of drug-dependent antibodies for defined RBC antigens. This prompted us to reinvestigate all nomifensine-induced RBC antibodies that were available in our laboratory. In fact, most antibodies studied required certain RBC antigens for full reactivity. This indicated that the target cells in this syndrome must supply a part of (in the case of drug-dependent antibodies) or even the entire area (in the case of drug-induced autoantibodies) for sensitization and for the subsequent attachment of the resultant antibodies. This is corroborated by several lines of evidence. First, the drug-dependent antibodies recognize only one cell type, ie, RBC and not platelets. Second, binding characteristics onto the cells exactly resemble that of true RBC antibodies in that absorbed and eluted drug-dependent antibodies can be shown to rebind by their F(ab) rather than by their Fc portion.[6] Third, the results of the Scatchard plot analysis in this study speak for specific rather than for unspecific attachment of the antibodies to the cells. In our experience, unspecific attachment of IgG antibodies to RBC cause usually weak reactions in the antiglobulin test and in radioimmunoassays. Fourth, the heterogeneity of the ndab among patients or even in the same patient (drug-dependent antibodies and/or autoantibodies) corresponds to that seen in animals sensitized with hapten-protein conjugates. Finally, some workers have, in isolated cases, reported specificity of drug-dependent antibodies.[12,25,26]

Thus we have reason to assume that loose binding of drugs (haptens) on cell surfaces is sufficiently immunogenic for sensitization against cell-drug complexes and/or against the cells alone. The failure to recognize in vitro the causative drugs on target cells does not preclude an interaction with blood cells in vivo. Continued provision of drug into the circulation might maintain the unbound drug concentration at a level favoring such association, whereas a less favorable gradient develops in an in vitro test carried out at a single drug concentration. If this is true, it is likely that a prolonged loose attachment of drugs and/or their metabolites onto the cells can alter natural antigens in such a way that allows the production of heterogeneous antibodies.

ACKNOWLEDGMENT

We are indebted to Professor S. Seidl (Frankfurt, FRG) for supplying Rh_{null} RBC, to Dr B. Habibi (Paris) for generous provision of serum 1, to Dr P.A. Tippett and Dr G.L. Daniels of the Medical Research Council Blood Group Unit (London) for the opportunity to use some of their collection of RBC of rare phenotype, and to the manufacturer Hoechst Pharmaceuticals (Frankfurt, FRG) for the drug. The excellent technical assistance of Karin Kissel and the secretarial expertise of Inge Lenssen are gratefully acknowledged.

Cytoplasmic Immunoglobulins in Chronic Lymphocytic Leukemia B Cells

By G. Pianezze, I. Gentilini, M. Casini, P. Fabris, and P. Coser

It is generally assumed that chronic lymphocytic leukemia of B cell origin (B-CLL) is characterized by the presence of surface membrane immunoglobulins (SmIg) and by the absence of cytoplasmic immunoglobulins (CyIg). In a variable number of cases SmIg are not detectable because of their low density on the cellular surface. Because a constant presence of CyIg in 20 subjects suffering from B-CLL has been reported recently, we reexamined 15 SmIg-negative and 10 SmIg-positive B-CLL patients by SmIg and CyIg determinations. We used a direct immunofluorescence method on peripheral blood mononuclear cells for the detection of SmIg and, after fixation, for CyIg. CyIg were detectable in 24 out of 25 cases, with a fluorescence intensity ranging from weak to moderate. The existence of frequent negative results for CyIg determination in B-CLL reported in the literature probably depends on the low sensitivity of the method used. We conclude that CyIg determination is useful in phenotyping every B-CLL patient, especially SmIg-negative ones.

© 1987 by Grune & Stratton, Inc.

CHRONIC LYMPHOCYTIC LEUKEMIA (CLL) is a malignant proliferation of monoclonal lymphocytes of B cell origin in most instances.[1,2] It is generally accepted that B-CLL cells are characterized by the presence of surface membrane immunoglobulins (SmIg), the absence of cytoplasmic immunoglobulins (CyIg), the presence of mouse red cell receptors, and a predominance of receptors for $C3_d$ over those for $C3_b$.[3,4]

It is also common knowledge that, in the majority of SmIg-positive B-CLL, the intensity of surface immunofluorescent staining varies from weak to moderate,[5] and if quantitatively measured, the amount of SmIg appears to range from a quarter to a tenth when compared with that of normal lymphocytes.[6] A variable percentage (0% to 30%) of SmIg-negative B-CLL has been described by various authors.[4,7-9] To explain this finding, it is generally assumed that the density of SmIg on B cells in such cases is so weak that it is not detectable by common immunofluorescence methods. In such cases it is not possible to demonstrate the monoclonality of the B lymphocyte population supposed leukemic.

In recent publications[10,11] the presence of CyIg in B-CLL cells is described. In one of them the authors affirm that CyIg determination is superior to SmIg determination to prove the monoclonality of leukemic cells.[10] This statement seems to be in contrast with the current opinion; for that reason we decided to check it in our laboratory by reexamining a group of patients affected by B-CLL.

MATERIALS AND METHODS

Patient population. We studied 25 patients previously diagnosed as having B-CLL. This group included all patients in whom the presence of SmIg could not be demonstrated (15 cases) and others chosen at random among those SmIg-positive (ten cases). At diagnosis all patients showed a lymphocyte count above 10×10^9/L in peripheral blood (PB). Diagnosis had been made on the basis of typical clinical and laboratory findings. All patients were staged with the classification of Rai and colleagues.[12] Table 1 shows the principal clinical and laboratory findings of the patient population at diagnosis.

Surface markers. The mononuclear cells from B-CLL patients were separated from PB by a density gradient (Ficoll-Hypaque).[13] The presence of SmIg on mononuclear cells was determined through a direct immunofluorescence method[14] using fluorescein-conjugated antisera specific to human light and heavy chains (Dako Corp, Santa Barbara, CA). Fluorescence was always examined using both a fluorescent microscope (Ortholux with a xenon lamp, 75 W; Leitz, Wetzlar, Germany) and a laser cytofluorograph (Spectrum III:

Blood, Vol 69, No 4 (April), 1987: pp 1011-1014

Ortho Diagnostics, Westwood, MA). The mononuclear cells were tested with the monoclonal antibodies OKDR, OKT1 (Ortho Pharmaceuticals, Raritan, NJ), and Leu 1 (Becton Dickinson, Mountain View, CA) with the direct and indirect immunofluorescence methods recommended by Ortho Diagnostics for their cytofluorograph.

CyIg. Mononuclear cells were washed three times with phosphate-buffered solution (PBS) and smeared on slides by cytocentrifugation. The slides were subsequently fixed for 20 minutes in absolute methanol at 4°C and air-dried. The cell smear was then covered with chain-specific fluorescein-conjugated antisera (Dako) optimally diluted (1:40 was, in our experience, the optimal dilution). After 30 minutes' incubation at room temperature the slides were washed three times in PBS on a mechanical agitator (five minutes for each washing); at the last washing an Evans' blue solution (one drop every 100 mL PBS) was added as a counterstain. The slides were mounted in glycerol-PBS and observed under a fluorescent microscope.

To exclude the possibility that the fluorescence observed with the method for CyIg determination was due to SmIg, we used a technical procedure called neutralization. The suspension of mononuclear cells was previously incubated with an antihuman immunoglobulin antiserum (without fluorescein) for 30 minutes, then cytocentrifuged on microscope slides, fixed, and incubated for another 30 minutes with chain-specific fluorescein-conjugated antisera. That way the SmIg were neutralized by the unmarked antibody, and after fixation, the marked antibody could detect only the CyIg. We used T-CLL cells as negative controls for both SmIg and CyIg.

RESULTS

Data concerning SmIg are compared with those related to CyIg in Table 2, which shows that CyIg were detectable in 24 out of 25 cases (in three of them we could detect μ-type heavy chains but no light chains). In all cases, the fluorescence intensity for CyIg in the majority of cells, even if weaker than that expressed by more differentiated subtypes of the B cell line (plasma cells and plasmacytoid lymphocytes), allowed a clear distinction between positive and negative cells (Fig 1). Only a fraction of cells variable from 1% to 3% showed a strong fluorescence intensity.

Keeping in mind the difficulty in locating cell structures through conventional optical microscopy and because the effect of fixation on SmIg distribution is not completely known, we have considered the possibility that the positiveness detectable with our CyIg method might be attributable to SmIg, even if their fluorescence distribution patterns are always completely different. SmIg neutralization with unmarked antibodies excluded such a possibility; as a matter of fact, after neutralization SmIg were no longer detectable, whereas CyIg did not show any reduction in fluorescence intensity (Fig 2).

DISCUSSION

The results of our investigation substantially agree with the data published by Han et al[10] who found monoclonal CyIg in all 20 cases of B-CLL examined. In the same article they reported that in each B-CLL patient the intensity of SmIg fluorescence was moderate to strong. In some cases it was not easy to demonstrate the monoclonality of the leukemic population, probably because of nonspecific

*This patient showed a serum M component.

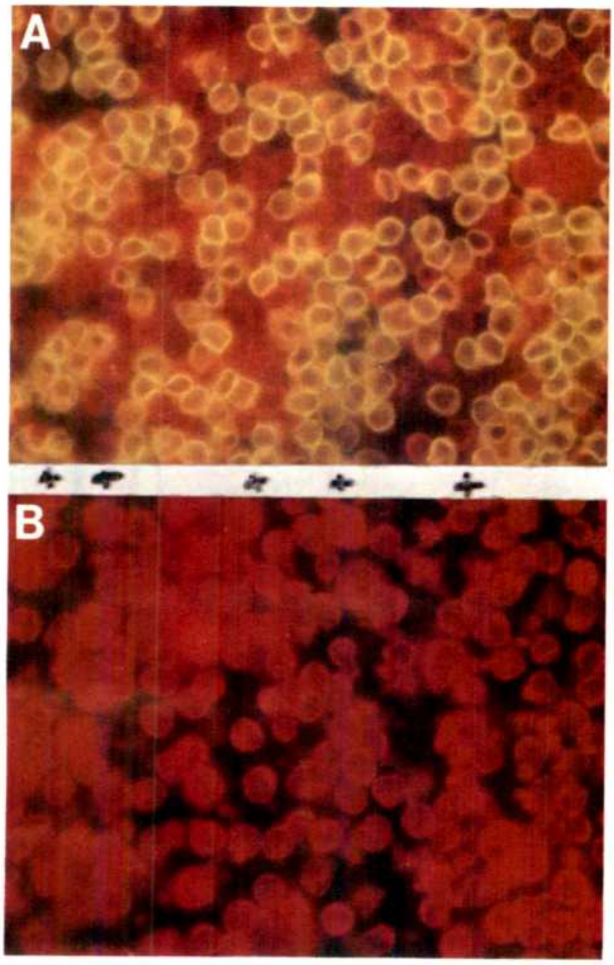

Fig 1. The photomicrograph (original magnification × 400) shows the results of CyIg immunofluorescence staining in case 9. (A) Positive staining with an anti-κ antiserum. (B) Negative staining with an anti-λ antiserum.

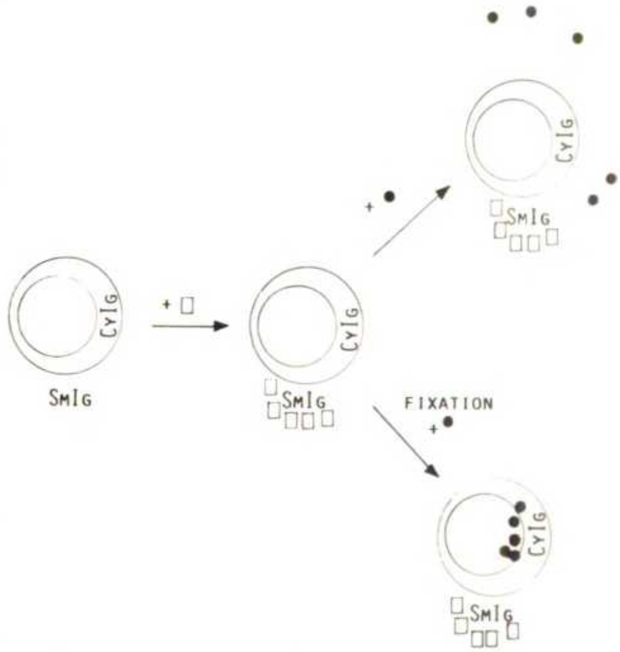

Fig 2. The non-fluorescein-conjugated antihuman immunoglobulin antiserum (□) reacts and neutralizes the SmIg. Under such conditions an FITC-conjugated antihuman immunoglobulin antiserum (●) cannot detect either the SmIg or the CyIg. Immunofluorescent staining will be negative, thus confirming the SmIg neutralization. After fixation, an FITC-conjugated antihuman immunoglobulin antiserum (●) is able to penetrate into the cell and detect the CyIg. Immunofluorescent staining will therefore be positive.

absorption of serum immunoglobulins by Fc receptors. They affirm that CyIg determination is superior to SmIg determination in B-CLL cell phenotyping because fixation suppresses the activity of Fc receptors.

On the other hand, we noticed the usefulness of CyIg determination in B-CLL cells, particularly when SmIg detection was not possible as a consequence of their low density on the cellular surface. Also, Schroff et al[11] reported the presence of monoclonal CyIg in all three cases examined of SmIg-negative B-CLL. Koziner et al[4] reported constant negative results for CyIg determination in 60 cases of B-CLL, whereas Gourdin et al[15] demonstrated, by immunoelectron microscopy, monoclonal CyIg only in B-CLL with serum M component. Furthermore Rudders[16] had reported the presence of monoclonal CyIg in 11 cases of B-CLL out of 26, and only four of them had serum M component.

To explain these conflicting results among the different reported findings, we should admit either the existence of B-CLL with a different CyIg phenotype (positive or negative) or a different sensitivity of the methods used. The second hypothesis seems to be more acceptable since a spatiotemporal clustering of so many B-CLL with the same CyIg phenotype appears statistically unlikely.

There is increasing evidence demonstrating that cells from B-CLL patients secrete monoclonal immunoglobulins. Using more sensitive methods than traditional ones, their presence may be demonstrated in the serum and/or urine of such patients in a percentage of cases ranging from 53% to 73%, depending on the method used.[17,18] These findings suggest an intrinsic but poorly developed secretory capacity in B-CLL cells and therefore indirectly justify the presence of monoclonal CyIg in the leukemic cells.

Gourdin et al[16] considered that, excluding cases with a high M component, the presence of monoclonal immunoglobulins in serum of typical B-CLL depends on a small leukemic subpopulation that is also positive for CyIg. On the other hand, on the basis of our results and of those of Han et al,[10] this property seems to be a characteristic of a wide majority of the leukemic population. In conclusion, even if we recognize the necessity of finding an adequate explanation for the reported discrepancies among data in the literature, in our hands the CyIg determination is a valid help in improving the sensitivity and specificity of B-CLL phenotyping.

ACKNOWLEDGMENT

We are particularly grateful to Sandro Pasutto and to Carlo Moeseneder-Frajria for the excellent technical assistance. We also wish to thank Sonia Doria and Rita Musmeci for typing the manuscript.

Total Body Irradiation and High-Dose Etoposide: A New Preparatory Regimen for Bone Marrow Transplantation in Patients With Advanced Hematologic Malignancies

By K.G. Blume, S.J. Forman, M.R. O'Donnell, J.H. Doroshow, R.A. Krance, A.P. Nademanee, D.S. Snyder, G.M. Schmidt, J.L. Fahey, G.E. Metter, L.R. Hill, D.O. Findley, and I.J. Sniecinski

In a phase I/II study, 47 patients (median age, 24 years) with hematologic malignancies (33 patients with acute leukemia not in first remission and 14 patients with other advanced malignant hematologic disorders) were treated with total body irradiation and high doses of etoposide (VP16-213) followed by bone marrow transplantation. At the time of analysis, 21 patients were alive, and 19 of them were in continued complete remission for 101 days to >40 months (median, 12 months). The actuarial disease-free survival rate of the 33 acute leukemia patients is 43% (2 SEM, 18%) and the actuarial relapse rate is 32% (2 SEM, 20%). Five of the 14 patients with the other hematologic malignancies are alive, and four of them continue to be free of disease for 8 to 27 months. Pharmacokinetic studies established a strong correlation between the administered drug doses and their plasma levels and also demonstrated complete drug clearance prior to marrow grafting. An etoposide dose of 60 mg/kg body weight was found to be the maximum tolerated dose. This new preparatory regimen was well tolerated and was not associated with specific acute or long-term regimen-related toxicities. Our data suggest that total body irradiation with high-dose etoposide presents a viable alternative to other preparatory regimens. The role of this novel combination remains to be defined by future prospective randomized trials.

RECURRENCE of the underlying malignancy after bone marrow transplantation (BMT) is the leading cause for failure in patients who are not in first complete remission (CR) of acute leukemia or no longer in the chronic phase of chronic myelocytic leukemia (CML) when preparation for BMT is begun. Disease-free survival rates for such candidates after myeloablation and immunosuppression with total-body irradiation (TBI) and high-dose cyclophosphamide followed by BMT range from 10% to 40%.[1-9] With the aim of reducing the relapse rate without increasing regimen-related toxicities, we have developed a preparatory regimen consisting of TBI and high doses of the epipodophyllotoxin-derivative etoposide (VP16-213). Etoposide is almost exclusively marrow toxic and has proven activity against malignant cells if administered in standard doses to patients with relapsed hematologic malignancies[10-16] or in high doses followed by autologous bone marrow rescue.[17] Another advantage is its ability to penetrate into the CSF after high-dose intravenous administration.[18] The new combination, TBI with etoposide, was tested in a phase I/II study on 33 patients with acute leukemia who either had never attained CR or had relapsed at least once; in addition, 14 patients with other poor-risk hematologic malignancies were entered onto this study.

PATIENTS AND METHODS

Patients. Between March 1983 and April 1986, 47 patients (median age, 24 years; range, 1 to 47 years) with hematologic malignancies were prepared for BMT with TBI and high-dose etoposide. Twenty patients had acute nonlymphoblastic leukemia (ANLL): fifteen either had failed to ever attain CR with chemotherapy or had relapsed after successful remission induction; five were in second CR (Table 1). The subtyping of ANLL was performed according to French-American-British (FAB) criteria.[19] Thirteen patients had acute lymphoblastic leukemia (ALL): eight either had not entered a first CR in spite of repeated remission induction attempts or were in relapse; five patients were in second or third CR (Table 2). Patients identified as "induction failure" had received at least two courses of combination chemotherapy without attaining CR. The ten patients with acute leukemia who were in second or third CR at the time of BMT previously had first remissions that lasted 2 to 36 months (median, 7 months), and all had relapsed while receiving maintenance chemotherapy. In addition, 14 patients with other hematologic malignancies (Table 3) were enrolled in this study: two had refractory anemia with excess blasts (RAEB), two had refractory anemia with excess blasts in transition (RAEBIT), five had CML in accelerated or blastic phase, two had chronic myelomonocytic leukemia (CMMoL), two had Hodgkin's disease (HD) refractory to radiation and repeated courses of combination chemotherapy, and one patient had myelofibrosis/sclerosis (MF/S). Patients with myelodysplastic syndromes were classified according to a previously published system.[20]

Preparatory regimen. To 39 patients, TBI was administered in 11 fractions of 120 cGy between day −7 and day −4 to a total dose of 1,320 cGy.[21] An electron boost of 400 cGy was given to the testes on day −7 and one of 300 cGy twice daily to the chest on days −5 and −4. Because of limited availability of the linear accelerator, the remaining eight patients received a single-dose TBI regimen (750 cGy at 26 cGy/min) on day −5.[22] Etoposide was given by a four-hour infusion (1 mg etoposide/mL saline) on day −3 (Fig 1). Because of the instability of this drug, infusion bottles were changed every hour during the four-hour infusion period. Vigorous hydration

BMT

Fig 1. Preparatory regimen consisting of TBI delivered between days −7 and −4 and infusion of high-dose etoposide (VP16) on day −3 followed by BMT on day 0.

(150 mL/m^2/h) and diuresis were performed for 72 hours after it was observed that etoposide could lead to hemorrhagic cystitis. Following a dose escalation schema, five patients were treated at level I (25 to 30 mg/kg), seven at level II (40 mg/kg), five at level III (50 mg/kg), seven at level IV (60 mg/kg), and seven at level V (70 mg/kg). After level IV was established as the maximum tolerated dose, another 16 patients received etoposide at 60 mg/kg. During and after drug administration, blood specimens were collected and analyzed for etoposide plasma levels by using high-performance liquid chromatography.[23]

Marrow transplantation. For 46 patients their respective histocompatible siblings and in one case (unique patient no. 228) an identical twin served as bone marrow donors. On day 0, the day of BMT, marrow was harvested from the donors, filtered for removal of particles, and administered intravenously to the recipients.[24] In the case of four recipients who had a major blood group mismatch with their donors, the red cells were removed from the marrow aspirates by centrifugation in a cell separator.[25]

Post-BMT care. Supportive care after BMT was provided as described previously[26] except that the patients on this study did not receive prophylactic granulolcyte support. Nonabsorbable antibiotics were given for gastrointestinal decontamination to all patients on this study.[27] Posttransplant immunosuppression for prevention of graft-*v*-host disease (GVHD) consisted of methotrexate/prednisone in 16 patients and of cyclosporine A/prednisone in 30 patients. Twelve patients who received methotrexate/prednisone and nine patients taking cyclosporine A/prednisone participated (along with 86 other leukemia patients) in a prospective randomized trial comparing these two drug combinations.[28] GVHD was graded according to previously described criteria.[29]

Grading of toxicity and performance status. The acute and subacute toxicity encountered during this study was graded according to generally accepted criteria.[30] The performance status was scored following the Karnofsky system.[31]

Statistical evaluation. The analysis of actuarial survival in continued CR and of probability for relapse were done by nonparametric estimation from incomplete observations.[32]

Approval. All clinical research protocols involved in this study had been approved by the Institutional Review Board of the City of Hope National Medical Center. Patient entry to study was contingent upon prior written informed consent.

RESULTS

Pharmacokinetic studies. Plasma etoposide levels rose steeply during the time of intravenous drug administration, followed by an equally rapid clearance ($t\frac{1}{2} = 7.5$ hours). Approximately 50 hours after etoposide infusion no appreciable amounts of the drug could be detected (Fig 2). After another 24 hours, the marrow graft was infused. The peak etoposide plasma levels ($r = .97$, $n = 15$) and the areas under the curves ($r = .74$, $n = 14$) of the patients in whom pharmacokinetic studies were carried out correlated well to the amount of drug administered. The complete pharmacokinetic data including drug excretion results will be presented elsewhere (J.H. Doroshow et al, in preparation).

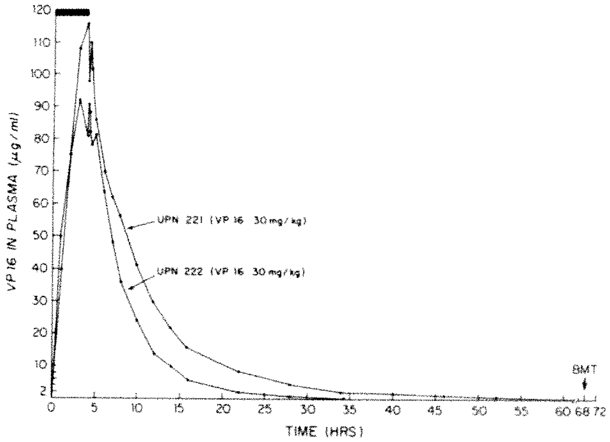

Fig 2. Etoposide (VP16) plasma levels (in μg/mL) of two patients (UPN 221 and 222) who received 30 mg etoposide/kg body weight by infusion over four hours (black horizontal bar). BMT was performed 68 to 72 hours after the beginning of drug administration.

Toxicity data. A transient, sometimes painful, rash (grade 2), mostly localized to the palms, soles, and periorbital area occurred at higher dose levels and lasted from four days to 3 weeks. Nausea and vomiting (grade 1 to 2) lasting for several hours occurred in patients who had received either 60 or 70 mg etoposide/kg body weight. Hypotension (grade 1) was encountered in one patient, presumably due to too vigorous diuresis with furosemide. No cases of arrhythmia were observed. Four patients developed hemorrhagic cystitis (grade 2), which was avoided in subsequent patients by maintaining a high urine flow for three days after etoposide infusion. We did not encounter any episodes of clinically significant metabolic acidosis. During the time of marrow aplasia, 41 patients developed clinical sepsis, ie, temperature >38.5°C in the absence of neutrophils. These 41 patients were treated with systemic broad-spectrum antibiotics. Severe stomatitis (grade 3 to 4) necessitating intermitten intravenous administration of narcotics occurred in most patients receiving the two highest drug doses. Stomatitis resolved in all patients at the end of the aplastic phase, ie, after 2 to 4 weeks. Two of the seven patients treated with 70 mg etoposide/kg developed severe jaundice and liver failure (grade 4) without signs of GVHD or venoocclusive disease. No neurotoxicity was observed in any of the 47 patients entered onto this study. The acute toxicity data are summarized in Table 4. No regimen-specific long-term toxicity was encountered. Two patients (UPN 221 and 245) have developed a clinical picture compatible with the chronic obstructive lung disease that is sometimes seen in recipients of allogeneic marrow grafts.

Engraftment. With the exceptions of one patient who had only transient signs of engraftment (UPN 270) and one patient with persisting malignancy (UPN 291) all BMT recipients showed a rise of WBC counts to >1,000/μL within 11 to 23 days (median, 14 days). Genetic marker analysis

demonstrated hematopoiesis to be entirely of donor origin in all cases except for the two aforementioned patients with graft failure (UPN 270) or with persisting malignancy (UPN 291). Three patients (UPN 222, 233, and 234) have become stable hemopoietic chimeras as reported elsewhere.[33]

Survival results. At the date of evaluation (August 1, 1986), 16 of the 33 patients with acute leukemia were alive, and 15 were in continued CR. The minimum follow-up of patients surviving in continued CR was 101 days, and the maximum was 40 months (median, 12 months). As shown in Fig 3, the actuarial disease-free survival rate for acute leukemia patients was 43% (2 SEM, 18%). Five of the 14 patients with hematologic malignancies other than acute leukemia were alive, and four of them were in continued CR for 8 to 27 months.

Dose-effect relationship. The relationship between the doses of etoposide administered to the patients in the various groups (dose levels I to V) and the incidence of relapse and survival in these groups is summarized in Table 5.

GVHD. The following incidence of acute GVHD was observed: grade 0 in 17 patients, grade I in ten patients, grade II in ten patients, grade III in seven patients, and grade IV in two patients; ie, the incidence of no or mild acute GVHD (grade 0 or I) was 59% and of moderate-to-severe acute GVHD (grade II to IV) 41%. The sample size is too small to permit a separate evaluation of the two GVHD regimens utilized in this study. Three patients (UPN 221, 234, and 245) have developed chronic GVHD that is improving with continued therapy with cyclosporine A and prednisone.

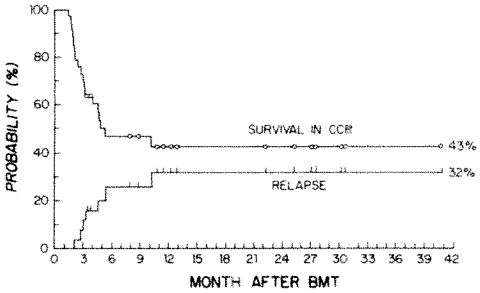

Fig 3. Probability of survival in CCR and probability of relapse after BMT observed in 33 patients with acute leukemia who were treated while not in first remission. Open circles and tick marks denote patients surviving in CCR.

Causes for failure. Fourteen of the 47 patients on study suffered a relapse of their underlying malignancy. Seven patients with acute leukemia relapsed as did seven who had other hematologic malignancies. Five of the relapses occurred in the eight patients who had received single-dose TBI. The earliest relapse was observed 1 month and the latest 10 months after BMT. As illustrated in Fig 3, the actuarial relapse rate for patients with acute leukemia was 32% (2 SEM, 20%). Thirteen patients died of respiratory failure due to interstitial pneumonia that was preceded by an episode of acute GVHD in eight and was associated with a protracted course of sepsis in one patient; the other four patients with interstitial pneumonia did not have acute GVHD. Marrow graft failure after initial engraftment occurred in one patient. The causes of failure are summarized in Table 6.

DISCUSSION

A novel myeloablative/immunosuppressive regimen has been designed and evaluated in a 3-year trial. This investigation has resulted in an excellent survival rate in continued CR of 43% for patients with acute leukemia who were not in first CR when entered onto this study. Our approach differs from previously used preparatory regimens with respect to its chemotherapeutic component in that cyclophosphamide has been replaced by etoposide.

Our pharmacokinetic studies have demonstrated that the drug doses administered correlate well with the attained plasma levels and, more importantly, that etoposide was completely eliminated prior to the time of marrow infusion. It seemed prudent to await total clearance in order to avoid any stem cell injury from residual etoposide.

The toxicity studies carried out in the 47 enrolled patients indicate that high doses of etoposide are well tolerated up to 60 mg/kg body weight. The fact that almost 90% of the

Table 5. Relationship Between Etoposide Dose Levels, Relapse, and Survival

Dose Level (mg/kg)	Relapse (%)	Survival (%)
I. 25-30	1/5 (20)	3/5 (60)
II. 40	4/7 (57)	3/7 (43)
III. 50	0/5 (0)	3/5 (60)
IV. 60	6/23 (26)	11/23 (48)
V. 70	3/7 (43)	0/7 (0)

patients on this study required treatment with systemic broad-spectrum antibiotics is not surprising considering their previous courses of combination chemotherapy and their hematologic status when preparation for BMT was begun.

Based on the toxicities observed, the drug dose of 60 mg/kg was considered the maximum tolerated dose that will also be used in our future studies. In general, regimen-related toxicities have been quite modest; this is best demonstrated by the fact that the earliest death of any patient on this study occurred on day +47 after BMT. The nonleukemic causes for failure were almost exclusively due to expected complications related to allogeneic BMT, ie, interstitial pneumonia in 13 patients, which occurred most frequently after an episode of acute GVHD. The lack of regimen-related long-term toxicities was particularly encouraging.

In combination with an established fractionated TBI method, this regimen has led to a complete response in all patients on this study except for the single case of a child with congenital myelodysplasia characterized by multiple clonal abnormalities (UPN 291). The actuarial relapse rate of 32% can be considered relatively low in comparison with other pretransplant regimens.[1-9] All leukemic recurrences in this study have so far occurred within the first year following BMT, an intriguing observation that warrants longer observations and further studies. Five of the 14 relapses occurred among the eight patients who had received single-dose TBI. These eight patients had been entered into our BMT program on an emergency basis because of their rapidly deteriorating hematologic status. Our limited linear accelerator capacity precluded treatment following the fractionated irradiation regimen. It cannot be decided whether the overall relapse rate would have been lower had those eight patients been treated with the fractionated TBI method.

Our study indicates that the combination of TBI with etoposide is a promising alternative to cyclophosphamide-containing regimens. On the other hand, our investigation leaves a number of problems still unsolved: the two leading causes for failure after any type of preparatory regimen continue to limit posttransplant survival in continued CR, namely, interstitial pneumonia and recurrence of the underlying malignancies. Our study also does not answer the question whether 60 mg etoposide/kg is a more effective dose than, for example, 30 mg/kg. The heterogeneity in hematologic condition and status of the candidates enrolled, the number of patients at the various dose levels, and the length of follow-up does not allow a definite answer to the dose-effect question. However, in view of the toxicity data (Table 4) and the relapse and survival results (Table 5), it seems that 60 mg etoposide/kg is the maximum tolerated dose that is associated with a relatively low relapse rate (26%) and favorable survival (48%). It seems not likely that further dose escalation would result in improved disease-free survival figures.

Finally, it cannot be stated that TBI/etoposide is ultimately better than any of the other previously or currently used preparatory regimens. This issue remains to be dealt with by appropriately designed future prospective randomized studies.

Erythropoietic Repopulating Ability of Stem Cells From Long-Term Marrow Culture

By David E. Harrison, Charles P. Lerner, and Elaine Spooncer

Hemopoietic precursors are heterogenous with respect to their capacity for self-renewal and long-term repopulating ability. Bone marrow cultures produce a variety of precursors over many weeks, including CFU-S; however, it is important to determine whether these populations retain the functional ability shown by fresh marrow. The most primitive precursor or stem cells have the most long-term repopulating ability. We here describe direct measurements of this ability in cells from marrow cultures by using competitive repopulation assays. Cultured adherent cells repeatedly showed less capacity than fresh marrow cells to repopulate erythropoiesis in irradiated recipients, whereas cultured suspension cells consistently had less capacity than adherent cells. Concentrations of macroscopic CFU-S measured at nine or 12 days were similar in cultured adherent and suspension cells and generally lower than those in fresh marrow. In every experiment, the long-term repopulating ability of the marrow cells used was substantially reduced after transfer into tissue culture. Thus, primitive stem cells may not proliferate in such cultures despite extensive production of CFU-S and more differentiated cell types.

© 1987 by Grune & Stratton, Inc.

THE LONG-TERM CULTURE of mouse bone marrow cells is an established method for the prolonged maintenance, proliferation, and differentiation of hemopoietic precursor cells in vitro.[1-6] Analogies with hemopoiesis in vivo include the requirement for the stromal adherent layer that appears to fulfill the role of the hemopoietic environment.[2,3] Furthermore, most cells produced in vitro have been indistinguishable from their in vivo counterparts.[2,4] The hemopoietic precursors produced in vitro that are measured as macroscopic spleen colonies by the CFU-S assay of Till and McCulloch[7] are also identical in many respects to CFU-S from fresh bone marrow.[2] However, the self-renewal capacity of CFU-S from the suspension and, to a lesser extent, of CFU-S from the adherent cells appears to decline greatly during the first 3 weeks in vitro.[6]

Functional heterogeneity of the CFU-S compartment in vivo has previously been well documented by measuring their self-renewal[8,9] or their repopulating ability. Long-term repopulating abilities are low in CFU-S from the peripheral circulation,[10] in previously transplanted marrow cells,[11-13] or following recovery from sublethal irradiation,[13] which shows that the CFU-S assay detects a heterogeneous population of stem cells. Since CFU-S measures are not easy to interpret, we focused on directly testing the primitive stem cell function of long-term repopulation in cultured marrow cells compared with fresh marrow controls.

Repopulating abilities can be measured directly in a sensitive fashion by competitive repopulation.[10-14] Stem cell–depleted recipients were given cells from the various donors to be compared. Each also received a standard dose of competitor stem cells that produced a distinguishable product, in this case hemoglobin.[14] The percentage of donor hemoglobin in the recipient measured the repopulating ability of the donor cells over many months.

MATERIALS AND METHODS

Animal models. C57BL/6J (B6) and $WBB6F_1$ (their F_1 hybrid with WB/ReJ) mice were used. All mice were bred at The Jackson Laboratory, which is fully accredited by the American Association for Accreditation of Laboratory Animal Care. These strains possess different alleles at the β chain locus of the hemoglobin molecule and produce hemoglobins that can be separated by standard electrophoretic procedures.[14] Lethally irradiated $WBB6F_1$ recipients were injected with a standard dose of fresh marrow cells (competitor) mixed with the cultured bone marrow cells or fresh marrow controls (donor); the two components of the mixture were of the different genotypes. There is little or no hybrid resistance by $WBB6F_1$ mice against B6 cells.[15]

Long-term marrow cultures. Cultures were established with 6 to 21×10^6 bone marrow cells per flask in Fischer's medium, 20% vol/vol horse serum, and 10^{-6} mol/L hydrocortisone sodium hemisuccinate as described.[1,16] Cultures were maintained at 33°C in 5% CO_2 in air and fed weekly by removing half the growth medium and replacing it with fresh medium.[1] Cells removed in the growth medium were designated cultured suspension cells. Adherent cells from cultures were harvested and pooled by detaching the cells with a rubber policeman.[17]

Marrow and preparation assays. Fresh bone marrow suspensions were prepared by flushing femurs and tibias from donor mice into a buffered balanced salt solution.[11] All cells were filtered through HC3-110 Nytex cloth (mesh opening, 110 μm); then they were counted on a Coulter model ZB1 counter (Coulter Electronics, Hialeah, FL) after the red cells were lysed with Ultralyse (Clay Adams). Recipient mice were irradiated 15 to 18 hours prior to transplantation with a Shepherd Mark I ^{137}Cs irradiator at 220 rad/min. For CFU-S assays, B6 recipients were given 900 R, and $WBB6F_1$ recipients were given 1,000 R. The CFU-S assay was performed according to the method of Till and McCulloch[7]: three to six recipients per group were injected with 10^5 marrow cells in the lateral tail vein and checked after nine or 12 days as noted in the table captions. For competitive repopulation assays, $WBB6F_1$ recipients were given 1,200 R. Three to eight of these mice per group were injected with the following cell numbers, except as noted otherwise in the table caption: 2×10^6 fresh (competitor) B6 marrow cells from a single pool mixed with 1×10^6 from one of the three $WBB6F_1$

(donor) types—adherent cells or suspension cells from the culture or fresh marrow cells. Donor and competitor genotypes were reversed in one experiment. Seven to 14 weeks later and again 22 to 29 weeks after that, the hemoglobin types were determined in the recipient mice.

RESULTS

Figure 1A shows the numbers of suspension cells and adherent cells in WBB6F$_1$ +/+ bone marrow cultures all made from a single marrow cell pool and tested over a period of 16 weeks. Figure 1B demonstrates that concentrations of CFU-S were equivalent in the suspension cells and adherent layer and that concentrations in fresh bone marrow were consistently higher. The production of these cell types was comparable with other reports.[1-6,17-19] Fig 1C shows data from experiments using the donor adherent and suspension cells from these cultures or fresh WBB6F$_1$ +/+ donor marrow controls; doses of these were individually mixed with a standard dose of fresh B6 marrow competitor cells and injected into irradiated recipients. After 8 to 13 weeks, competitive repopulating abilities were shown by the percentages of donor-type hemoglobin in these recipients. Percentages from cultured cells declined to undetectable levels by 6 weeks of culture, although the adherent cells showed measurable repopulating abilities in subsequent weeks, notably at weeks 8 and 14 when they produced 28% and 32% of the total respectively. Fresh marrow controls consistently repopulated better than the adherent cells and produced 79% and 67% of the total hemoglobin content at weeks 8 and 14.

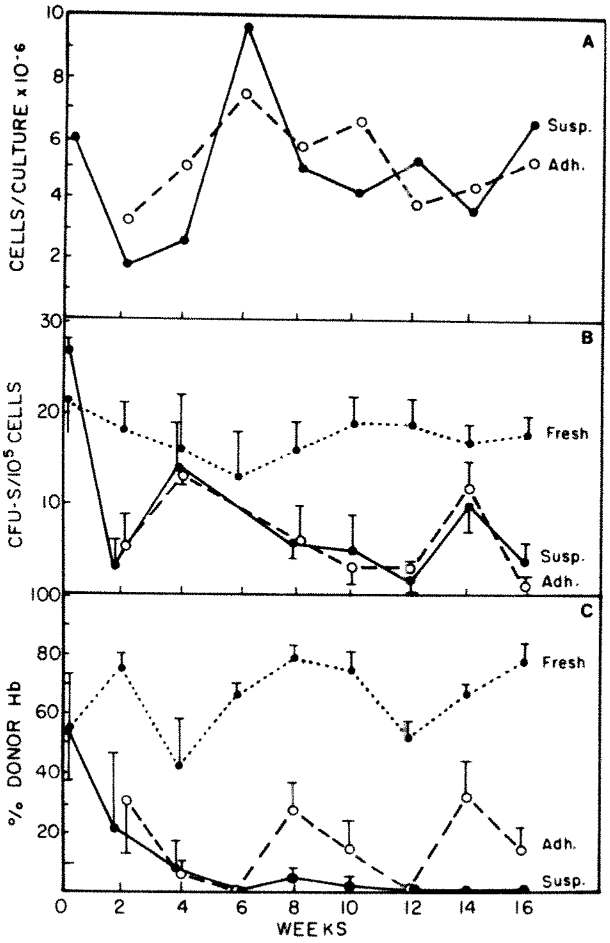

Fig 1. Forty long-term bone marrow cultures were established by using pooled femoral marrow from 3- to 6-month-old WBB6F$_1$ female mice. (A) Cell counts for culture suspension, ●—●; total numbers of cells per adherent layer, O---O, over a 16-week period of culture. (B) CFU-S number/10^5 cells: cultured suspension cells, ●—●; cultured adherent cells, O---O; fresh marrow cells, ●· · · · ·●. Points show mean values, and bars are the standard error for four mice at each point. (C) Percentage of donor-type hemoglobin in recipient mice 8 to 13 weeks after cell mixtures were injected in the competitive repopulation assay. WBB6F$_1$ donor cells were as follows: cultured suspension cells, ●—●; cultured adherent cells, O---O; and fresh marrow cells, ●· · · · ·●. Fresh B6 marrow cells were the competitor. Points show mean values, and bars are the SE for three to four recipients at each point.

Table 1 shows cumulative data over the last 10 weeks for the experiment in Fig 1. Numbers of CFU-S per 10^5 adherent and suspension cells were the same and averaged 31% of fresh marrow values. When recipients were checked 8 to 13 weeks after donor and competitor mixtures were injected, adherent cell–repopulating abilities averaged 20% of those shown by fresh marrow; suspension cells averaged less than 2% of fresh marrow values. When these data were shown in more detail in Fig 1C, adherent cell–repopulating abilities were highly variable. When the same recipients were checked after 22 weeks more (right hand column, Table 1), no donor hemoglobin was detected from cultured adherent cells except those collected at 14 weeks. The average repopulating abilities of adherent cells had dropped to 7% of those shown by fresh marrow, whereas those of suspension cells were undetectable.

Table 2 summarizes data in which genotypes were reversed. The donors were cultured B6 cells or fresh marrow controls that competed with fresh WBB6F$_1$ competitor marrow after 4 and 6 weeks in culture. Once again the adherent and suspension cells from culture had equivalent concentrations of CFU-S, yet the suspension cell–repopulating ability was very low, 4% and 0% of fresh marrow values. Adherent cell–repopulating abilities were 33% and 16% of fresh marrow values.

To determine whether the wide range of repopulating abilities shown by adherent cultured cells resulted from random variations in activities of primitive precursors in the separate culture flasks sampled, four more independent long-term marrow culture experiments were run (Table 3). The initial numbers of marrow cells per flask were about three times higher than those in Fig 1 and Table 1, and the same WBB6F$_1$ +/+ type of marrow donors were used. In assays of long-term repopulating ability by competitive repopulation in experiments 2, 3, and 4 (Table 3), the ratio of donor to competitor cells were 2, 4, and 2.5 times lower respectively for the fresh marrow donor than for the cultured suspension and adherent cells. This compensated for the poorer long-term repopulating abilities of the latter. After 7 to 14 weeks the percentages of donor-type hemoglobin produced by fresh marrow were two to five times higher (after adjusting for donor cell ratios) than percentages produced by cultured adherent cells; the latter competed 1.5 to 2.5 times

Table 1. Erythropoietic Repopulating Ability of Cultured WBB6F$_1$ Marrow

Origin of F$_1$ Donor Marrow	Total Cells/Culture (× 10^{-6})	CFU-S/10^5 Cells	Percentage of Donor-Type Hemoglobin After	
			8-13 wk	30-35 wk
Suspension	5.8 ± 0.9	5.5 ± 1.4 (7)	0.9 ± 0.6 (6)	0 ± 0
Adherent	5.7 ± 0.6	5.0 ± 1.9 (7)	14.3 ± 5.5 (6)	5.5 ± 5.5 (6)
Fresh marrow	—	16.7 ± 0.8 (7)	69.6 ± 4.1 (6)	77.0 ± 4.3 (6)

This table summarizes data shown in Fig 1 that was collected at 2-week intervals during 16 weeks in culture. Cultures were established with 6 × 10^6 pooled WBB6F$_1$ +/+ bone marrow cells per flask, and adherent cells were pooled from three flasks for testing at 2-week intervals. CFU-S data measured at nine days are summarized from 8 to 16 weeks in culture, and cell numbers and the percentage of donor-type hemoglobins are summarized from 6 to 16 weeks in culture. Values for fresh bone marrow are compiled from seven separate experimental time points, each with four recipients for CFU-S, and from six experimental time points for the percentage of donor-type hemoglobin, each with three to four recipients. The right hand columns summarize the percentage of donor-type hemoglobin in the same recipients 8 to 13 and 30 to 35 weeks after donor-competitor mixtures were transplanted. Only the data after 8 to 13 weeks were shown in Fig 1C. The major change after 22 weeks was the absence of hemoglobin produced by adherent cells from 8-, 10-, and 16-week cultures. Those from 14-week cultures continued to produce 33% ± 14% (4) donor hemoglobin compared with 71% ± 7% (3) from the fresh marrow control used at the same time. Data show mean values ± SE (number of experimental time points).

better than cultured suspension cells (Table 3). The advantage of fresh marrow was increased when percentages of donor-type hemoglobin were determined after 24 to 33 weeks in experiments 1 and 2. Numbers of CFU-S were determined at nine days in experiments 1 and 3 and at 12 days in experiments 2 and 4 due to reports that the latter may better represent the primitive stem cell populations.[9] As in previous experiments, CFU-S numbers underestimated the differences in repopulating ability. For example, in experiments 2 and 4, adherent cultured cells had 77% and 97% of the 12-day CFU-S as fresh marrow but 58% and 49% of the donor hemoglobin type at 7 to 14 weeks (Table 3).

DISCUSSION

The primitive stem cell function of competitive repopulation against fresh marrow was substantially reduced in adherent cells from long-term marrow cultures and further reduced in suspension cells. These findings are consistent with the results of Mauch and colleagues[6] who reported that CFU-S self-renewal capacities of suspension cells were extremely low and those of adherent cells were about threefold lower than those of fresh marrow from weeks 3 to 8 of culture. Schofield and Dexter[18] also found very poor self-renewal in CFU-S from the suspension. However, they found normal self-renewal in CFU-S from adherent cells, a conflicting result perhaps due to their use of spleen colonies in studying self-renewal. The most primitive stem cells may repopulate the marrow, not the spleen, of an irradiated recipient. Marrow precursor cells are studied by the long-term repopulation experiments in this report, and marrow was the source of cells whose self-renewal was studied by Mauch and colleagues.[6] The conclusion that stem cells in the adherent layer are less primitive than those in fresh marrow is supported by the loss of adherent cell–repopulating abilities between 7 and 14 weeks and 24 and 35 weeks in the same recipients (Tables 1 and 3). This also illustrates the value of measuring competitive repopulation over the long term so that measures are likely to represent truly primitive stem cells, although only erythrocyte function is assayed, and the possibility that erythroid rather than multipotential stem cells are measured is not formally eliminated.

The apparent reemergence of adherent stem cells with considerable long-term repopulating abilities after 14 weeks of culture in our studies (Fig 1C, Table 1) probably represents variability in individual cultures since cells were pooled from three separate (randomly selected) cultures for each time point. When more experiments were done and the cultures were started with about three times higher numbers of marrow cells, the relative repopulating abilities of cultured adherent compared with fresh marrow cells varied from about 20% to 50% (Table 3). This variability probably reflects the rarity of the true primitive stem cell and the random nature of its preservation among the bone marrow cells used to establish a culture.

Table 2. Erythropoietic Repopulating Ability of Cultured B6 Marrow

Origin of B6 Donor Marrow	Culture Duration (wk)	Total Cells/Culture (× 10^{-6})	CFU-S/10^5 Cells	Percentage of Donor-Type Hb*
Suspension	4	2.1	17.7 ± 0.3 (4)	0
Adherent	4	1.9	13.5 ± 0.5 (4)	11.5 ± 4.5 (2)
Suspension	6	5.9	3.4 ± 1.0 (3)	1.3 ± 1.3 (3)
Adherent	6	6.1	3.5 ± 0.3 (3)	5.3 ± 3.9 (4)
Fresh marrow	—	—	16.8 ± 2.3 (8)	33.0 ± 3.0†

Long-term bone marrow cultures were established from 10 to 15 × 10^6 pooled B6 femoral marrow cells per flask. After 4 and 6 weeks, cultured suspension and adherent cells were harvested. Their nine-day CFU-S were measured, and for the competitive repopulation assay, recipient mice were injected with 1 × 10^6 fresh WBB6F$_1$ competitor marrow cells from a single pool mixed from 2 × 10^6 suspension, adherent, or fresh B6 (donor) marrow cells. Data show mean values ± SE (number of recipients).

*Percentage of donor type hemoglobin in recipient mice 9 to 11 weeks after mixtures injected for the competitive repopulation assay.

†This value was determined from three separate experiments with four recipients each.

Table 3. Erythropoietic Repopulating Ability of Cultured WBB6F$_1$ Marrow Prepared in Four Separate Experiments

Origin of Donor Marrow	Culture Duration (wk)	Total Cells/Culture ($\times 10^{-6}$)	CFU-S/10^5 Cells	Percentage of Donor-Type Hemoglobin After	
				7-14 wk	24-33 wk
Experiment 1					
Suspension	8	11.1	2.9 ± 0.5	8 ± 8 (3)	0 ± 0 (3)
Adherent	8	9.0	4.4 ± 0.7	19 ± 5 (7)	15 ± 7 (7)
Fresh marrow	—	—	15.0 ± 1.2	89 ± 1 (4)	87 ± 5 (4)
Experiment 2					
Suspension	8	9.1	7.7 ± 0.4*	37 ± 12 (7)	49 ± 16 (4)
Adherent	8	4.3	8.7 ± 0.4*	72 ± 6 (9)	78 ± 6 (8)
Fresh marrow (×2)†	—	—	11.3 ± 0.8*	62 ± 4 (3)†	89 ± 4 (3)†
Experiment 3					
Suspension	8	2.3	7.8 ± 0.8	48 ± 9 (4)	—
Adherent	8	1.5	10.9 ± 1.0	68 ± 3 (4)	—
Fresh marrow (×4)†	—	—	17.8 ± 1.3	67 ± 6 (5)†	—
Experiment 4					
Suspension	4	7.3	12.5 ± 1.6*	29 ± 12 (4)	—
Adherent	4	4.6	20.3 ± 1.2*	82 ± 1 (3)	—
Fresh marrow (×2.5)†	—	—	21.8 ± 1.6*	67 ± 3 (5)†	—

Long-term bone marrow cultures were established from pooled WBB6F$_1$ +/+ femoral marrow cells using 21 × 10^6, 15 × 10^6, 16 × 10^6, and 19 × 10^6 cells per flask in experiments 1, 2, 3, and 4, respectively. After 4 to 8 weeks, cultured suspension and adherent cells were harvested. Their CFU-S were measured after nine or 12 days along with those of a fresh marrow control F$_1$ +/+ donor in three to six recipients each. For the competitive repopulation assay in experiment 1, recipient mice were injected with 2.0 × 10^6 fresh B6 competitor cells from a single pool mixed with 1 × 10^6 suspension, adherent, or fresh F$_1$ donor cells.

*Twelve-day CFU-S were measured in experiments 2 and 4, whereas nine-day CFU-S were measured in experiments 1 and 3.

†In experiments 2, 3, and 4, the ratios of the donor to competitor cells were, respectively, 2, 4, and 2.5 times lower for the fresh marrow control than for the cultured cells. Thus in experiment 2, 1.0 × 10^6 cultured donor cells were mixed with 1.0 × 10^6 competitor cells, and 1.0 × 10^6 fresh donor cells were mixed with 2.0 × 10^6 competitor cells. In experiment 3, 2.0 × 10^6 cultured donor cells were mixed with 1.0 × 10^6 competitor cells, and 1.0 × 10^6 fresh donor cells were mixed with 2.0 × 10^6 competitor cells. Experiment 4 was like experiment 2 except that 1.0 × 10^6 fresh donor cells were mixed with 2.5 × 10^6 competitor cells.

The consistent reduction in repopulating capacity of adherent cells may also be due to the mechanical disaggregation of hemopoietic tissue that occurs during culture establishment. Indeed, cells from the adherent layers of our cultures repopulated at least as well as marrow cells that had undergone one in vivo transplantation[11-13] in which analogous disruption of the tissue occurs, although it should be noted that at least 100 times more proliferation occurs in vivo. Both in vivo and in vitro, the stress of proliferation and differentiation may push the cells of highest repopulating ability to form cells with lower levels of repopulating ability. It is unlikely that the defects in cultured cells result from the absence of essential accessory cells or the presence of suppressing cells because both donor and competitor cells are grown in the same recipient in the competitive repopulation assay.

The superior repopulating ability and self-renewal of adherent cultured cells compared with cells in the suspension demonstrate why the stroma is essential to the prolonged duration of hemopoiesis in vitro[1-3,19] and confirm findings that the bulk of cells in the suspension are produced in and released from the adherent layer.[20] Although human bone marrow cells do not grow for prolonged periods in vitro, they produce cultures with adherent layers within which the more primitive multipotential cells are preferentially located.[21] Even cultured marrow suspension cells have been shown to save the lives of lethally irradiated mice.[22] However, any future use of human cultured cells for transplantation would best be performed by using cells of the adherent layer to enhance chances of long-term recovery.

Measurement of the number of CFU-S in cultured cells was not proportional to their ability to repopulate hemopoiesis. This was true in those measured at both nine and 12 days (Tables 1 to 3), although the latter are reported to show more primitive stem cell functions. Thus, quantitation by the CFU-S assay of stem cells grown in vitro does not necessarily reflect the maintenance of primitive stem cells. In order to grow the most primitive stem cells in vitro, procedures should be developed that increase the long-term repopulating abilities of the cultured cells. In the six separate experiments reported here, the repopulating abilities of cultured cells were always less than those of fresh marrow, and the total numbers of cells were much lower than the numbers of marrow cells used to initiate the cultures (Tables 1 to 3). Thus the cells responsible for repopulating ability do not appear to increase in long-term marrow cultures. Nevertheless, the cells of the adherent layer evidently provide a useful model in vitro for studying hemopoiesis in the bone marrow, especially that occurring after a single transplantation. In contrast, the CFU-S released into the suspension phase may be more functionally comparable with those in peripheral blood than in marrow.

The Hematologic Characteristics of Sickle Cell Anemia Bearing the Bantu Haplotype: The Relationship Between $^{G}\gamma$ and HbF Level

By Ronald L. Nagel, Srinivas K. Rao, Olga Dunda-Belkhodja, Mary M. Connolly, Mary E. Fabry,
Alan Georges, Rajagopal Krishnamoorthy, and Dominique Labie

Previous work has demonstrated that the HbS gene has appeared and expanded three times in Africa in three separate geographic locations and that these three distinct mutational events can be identified by linked DNA polymorphic sites (haplotypes) surrounding the abnormal gene. We have reported that the Senegalese and Beninian haplotypes differ in $^{G}\gamma$ expression, mean percentage of HbF, and percentage of dense cells. We now report on the third haplotype, the Bantu, and find that it has intermediate features, namely, the high mean percentage of HbF and low percentage of dense cells associated with the Senegalese haplotype, but with a low percentage of $^{G}\gamma$ expression similar to the Beninian haplotype. The distribution of percent HbF is quite different from Senegal haplotype-bearing sickle cell anemia patients since it covers a much wider range. The low $^{G}\gamma$ expression is also different from the Beninians since it contains a significant and unique cluster of individuals with lower than 38% $^{G}\gamma$. Interestingly, among the Bantu there is a strong correlation between HbF levels and $^{G}\gamma$ expression, which is not seen with the other haplotypes. These findings open the possibility that among the Bantu haplotype-bearing individuals two chromosomal types exist that define different levels of $^{G}\gamma$ and HbF expression. Further structural exploration of these two potential subhaplotypes is needed.

© 1987 by Grune & Stratton, Inc.

PRESENT EVIDENCE suggests that the HbS gene appeared in Africa at least three times and presumably expanded in frequency through the selective pressure of *Plasmodium falciparum* malaria. The best evidence for this hypothesis comes from the geographically segregated linkage disequilibrium of the HbS gene with three different β gene cluster haplotypes (the Senegal, the Benin, and the Bantu haplotypes).[1] That these are indeed the major haplotypes associated with the HbS gene is confirmed by the study of Jamaican and American sickle cell anemia (SS) patients.[2,3] This finding suggested the possibility that the HbS gene could be accompanied by a different set of linked epistatic genes in each of these three haplotypes. Indeed, we have reported previously that SS patients bearing the Senegalese haplotype have more HbF, less dense cells, and higher $^{G}\gamma$ expression than patients in which the HbS gene is linked to the Benin haplotype.[4] We report here on the hematologic and genetic characteristics of the third haplotype, the Bantu, and a comparison with the other two reveals that it is associated with yet another unique set of features.

METHODS

Samples were obtained, after informed consent, from all the unrelated attendants of the outpatient clinic who came without regard to present symptomatology after a public announcement. Patients with a history of painful crisis less than a week old were eliminated from the sample. The hematologic parameters were determined as previously described.[4] β Gene cluster and α gene haplotypes were determined by Southern blotting in the manner reported elsewhere[1] by using the *Hind*III detectable polymorphic site in the IVSII region of the γ genes, the *Hinc*II sites in the $\psi\beta$ gene region, and *Hpa*I site 3' to the β gene. In a subset of samples in addition, the *Hinc*II site 5' to ϵ, *Xmn*I 5' to γ, the *Pvu*II site 5' to $\psi\beta$, the *Ava*II in IVSII of the β chain and the *Bam*HI 3' to the *Hp*I site were determined. The α haplotype was determined by *Bam*HI digestion. Percoll-Stractan isopycnic gradients were made as described previously,[5] and the four classes of cells were defined as fraction 1 (Fl, mean corpuscular hemoglobin concentration [MCHC] less than 33 g/dL, densities less than 1.083 g/mL), fraction 2 (F2, MCHC between 33 and 37 g/dL, densities between 1.083 and 1.093 g/mL), fraction 3 (F3, MCHC between 37 and 42 g/dL, densities between 1.093 and 1.105 g/mL), and fraction 4 (F4, MCHC greater than 42 g/dL, densities greater than 1.105 g/mL). Fl contains reticulocytes and young cells, F2 reversible discocytes, F3 the unsicklable SS discocytes, and F4 the densest irreversible discocytes and the irreversibly sickled cells (ISC).

Percent HbF present as $^{G}\gamma$ was determined by a high-performance liquid chromatography method using a Vydac large-pore (300 Å) C_4 column, 4.6 × 250 mm (Separations Group, Hesperia, CA) and an acetonitrile/trifluoroacetic gradient. The HbF was prepurified by BioRex-70 (Bio-Rad, Richmond, CA) column chromatography.

Statistics were done with the help of an IBM-XT computer and the Statgraphics program (STSC-Plus-Ware, Rockville, MD) for plotting, frequency histogram, regression analysis, the two-sample *t* test, and cluster analysis.

RESULTS

We have studied 64 unrelated SS patients from the Central African Republic. Of these 128 chromosomes, 116 β genes were linked to the Bantu haplotype (90.6%), whereas 12 chromosomes were atypical and their characteristics will be reported elsewhere.

Hematologic and genetic characteristics of SS-bearing Bantu haplotype. We report here on the hematologic and genetic characteristics of 54 SS patients (mean age, 14 ± 6.3 SD) in whom the Bantu β gene cluster haplotype[1] has been demonstrated by defining five polymorphic sites. Of these 54 patients, 36 were females and 18 males, 26 were $\alpha\alpha/\alpha\alpha$

(48.4%), 22 were $-\alpha/\alpha\alpha$ (40.6%), and 6 were $-\alpha/-\alpha$ (11.1%). The gene frequency of the $-\alpha$ haplotype is then 0.315 among these patients, higher than that found among AA individuals in the Central African Republic,[6] which predicts that about 62% of patients with SS have concomitant α-thalassemia. This result is in agreement with earlier data that found the frequency of $-\alpha$ increased among sickle cell anemia patients as compared with the normal population,[7,8] which suggests a protective effect of α-thalassemia in terms of survival. This suggestion has been confirmed in several populations by the age dependence of the $-\alpha$ gene frequency,[6-8] although the data of others[9] have only partially confirmed this finding by observing four homozygotes among the patients over 50 years old.[10]

In Table 1 the hematologic and genetic characteristics of the total sample and of the sample separated according to α gene status are depicted. Prominent among the findings are the high percentage of HbF (10.4%) and the corresponding low percentage of F4 (8.9%) and ISC (8.7%). The HbF levels are significantly correlated with the level of F4 ($r = .320$, $P < .018$, n = 54) as previously demonstrated for SS patients with the Senegalese haplotype.[4] HbF also correlated with ISC ($r = .299$, $P < .027$), not surprisingly since the percentage of ISC in the total population correlates with the percentage of F4 very strongly ($r = .863$, $P < 4.4 \times 10^{-17}$). It is interesting to note that the correlation of the percentage of ISC *v* F4 had an r^2 of .86 for $\alpha\alpha/\alpha\alpha$ individuals but that the r^2 for $-\alpha/\alpha\alpha$ and $-\alpha/-\alpha$ patients was much lower (.32), which suggests that in concomitantly α-thalassemic individuals the percentage of ISC is a less accurate reflection of the percentage of dense cells.

The reticulocyte count was correlated with F4 in the total sample ($r = .304$, $P < .025$). The hematocrit (Hct) value was marginally correlated with the percentage of HbF ($r = .26$, $P < .05$) and the reticulocyte count ($r = .26$, $P < .05$).

The $^G\gamma$ ratio was 40.4% (±6.2 SD) in 54 patients studied, and no effect of α-thalassemia on this parameter is observed.

Table 2. Comparison of the Hematologic Characteristics of the Three Major Haplotypes Linked to HbS

Characteristics	Senegal*	Benin*	Bantu
n	28	41	53
Hct (%)	24.6 ± 3.1	24.2 ± 4.9	23.9 ± 3.7
HbF (%)	12.3 ± 5.3	8.0 ± 5.2	10.4 ± 4.9
F4 (%)	12.2 ± 8.8	17.0 ± 8.9	8.9 ± 8.1
ISC (%)	9.3 ± 5.3	14.3 ± 10.3	8.7 ± 9.4
$^G\gamma$ (%)	65.8 ± 8.9	44.8 ± 4.6	40.4 ± 6.2

Data are means ± SD. See the text for significance.

*Data from reference 4.

Table 2 compares the hematologic properties of the Bantu haplotype SS with the Senegalese and Beninians. The Bantu and the Senegalese share a high percentage of HbF and a low percentage of F4, even when the elevated frequency of α-thalassemia in the Bantu population is taken into account by comparing the non-α-thalassemic Bantu to the Senegalese in whom α-thalassemia is less prevalent. Nevertheless, they are different in that the Senegalese haplotype is linked to high $^G\gamma$ expression and the Bantu is linked to low $^G\gamma$ expression in the adult. Both haplotypes are in turn very different from the Beninian haplotype, which is characterized by low HbF and high F4 percentages.

The percentage of HbF among the Bantu is significantly different from the Beninian ($P < .009$), as are the percentage of F4 ($P < .00002$) and the percentage of ISCs ($P < .005$). The Bantu percentage of F4 was also significantly different from the Senegalese percentage of F4 ($P < .05$).

The distribution of the percent HbF among patients with sickle cell anemia is also different for the three haplotypes (Fig 1). The mode for the percentage of HbF among patients with the Benin SS haplotype is in the class between 2.6% and 5%, with a nongaussian distribution trailing off to higher percentages. In contrast, the mode for Senegal and Bantu haplotypes is 10.1% to 12.5%, although a higher proportion (33% *v* 25%) of Senegalese are found with a percentage of HbF greater than 10. The difference between these two groups is the lack of Senegalese SS with a HbF below 5%, a class that is populated by over 11% of the Bantu SS patients.

The relationship between percent HbF and percent $^G\gamma$. Figure 2 illustrates the relation between the percentage of $^G\gamma$ and the percentage of HbF for the patients bearing the Bantu haplotype and a comparison with the Senegalese and Beninian sickle cell anemia patients. Not all Senegalese SS are known to carry the Senegalese haplotype. For the Bantu SS restricted to individuals 5 years of age or older (n = 52), the

F2	39.7 ± 19.2	34.9 ± 21.2	44.1 ± 16.2	45.8 ± 22.3
F3	4.5 ± 3.3	4.7 ± 3.7	4.4 ± 2.9	4.4 ± 3.1
F4	8.9 ± 8.0	9.9 ± 10.5	7.9 ± 4.7	6.0 ± 3.0

Numbers (except for n = number of patients and sex) are mean ± SD.

*F1, F2, F3 and F4 are density-defined red cell SS fractions obtained from Percoll-Stractan isopycnic gradients.

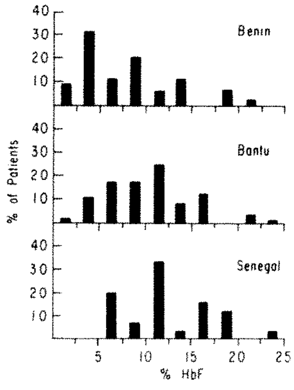

Fig 1. Frequency histogram of the percentage of HbF among SS patients bearing the Benin, Bantu, and Senegal haplotypes.

regression coefficient of percent HbF *v* percent $^{G}\gamma$ was 0.71 with a slope of 0.53 and a $t = 7.066$, $DF = 49$, and $P < .0001$. The presence or absence of α-thalassemia does not affect the results. Statistical cluster analysis of the data in Fig 2A reveals that there is a cluster of patients with less than 38% $^{G}\gamma$, scarcely represented among Beninian patients (2B). When the percent HbF in the group of Bantu SS patients with less than 38% $^{G}\gamma$ is compared with the percent HbF in those with more than 38.1%, the two-sample *t* test is highly significant, with a mean of 6.34 ± 2.46, and 12.46 ± 4.0, respectively, ($t = 5.909$, $DF = 50$, $P < 3.0 \times 10^{-7}$ (Table 3). In addition, the variance in the percent HbF among those above 38.1% $^{G}\gamma$ is much higher than that in those below 38% $^{G}\gamma$. The presence or absence of α-thalassemia, again, does not affect these findings. No differences in the mean of the Hct, reticulocyte count, F4, or ISC count was observed between these two subsets. The low percentage of F4 and ISC (despite the lower percentage of HbF) in the $<38\%$ $^{G}\gamma$ is due to a high proportion of α-thalassemics among these 18 individuals. In addition, full haplotypes (ten polymorphic sites) were determined in three subjects with less than 38% $^{G}\gamma$ and three with greater than 38% $^{G}\gamma$; no differences were observed, and all subjects were *Xmn* I-negative.

Most interesting are the calculations of regression curves below and above 38% $^{G}\gamma$. The *r* value for a correlation between HbF *v* ISC or F4 is (not significant) in the subset equal or less than 38% $^{G}\gamma$, whereas it is highly significant (for ISC = $r = -.53$, $DF = 29$, $t = -3.32$, $P < .005$; and for F4 = $r = -.45$, $DF = 29$, $t = -2.79$, $P < .01$) among those equal or higher than 38.1% $^{G}\gamma$.

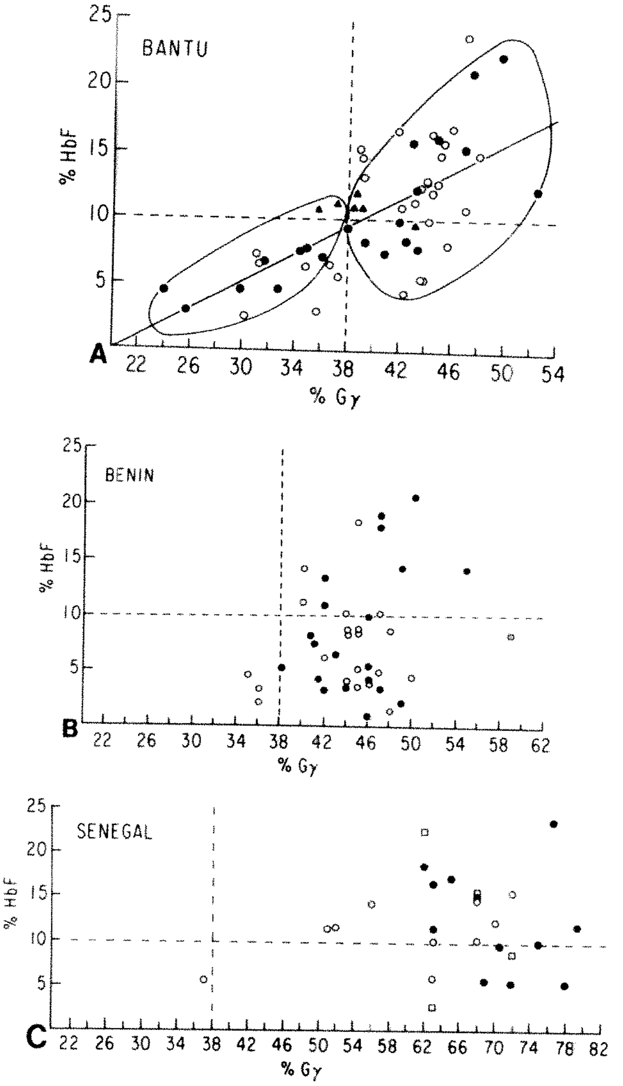

Fig 2. (A) Scatter plot of percent HbF *v* percent $^{G}\gamma$ for Bantu haplotype SS patients. ●, $\alpha\alpha/\alpha\alpha$; ○, $-\alpha/\alpha\alpha$; ▲, $-\alpha/-\alpha$. The straight line represents regression of the percentage of HbF on $^{G}\gamma$, which has an $r = .71$, slope $= 0.53$, $t = 7.066$, $DF = 49$, and $P < .0001$. Curved lines are clusters derived from a matrix that contains percent $^{G}\gamma$, percent HbF, and percent F4 using a Statgraphics program with the restriction that two clusters be formed. (B) Scatter plot of percent HbF *v* percent $^{G}\gamma$ for Beninian haplotype SS patients. ●, $\alpha\alpha/\alpha\alpha$; ○ $-\alpha/\alpha\alpha$. No significant correlation was found. (C) Scatter plot of percent HbF *v* percent $^{G}\gamma$ in SS patients originating in Senegal. ●, Senegal haplotype; □, atypical haplotype; ○, unknown haplotype. No significant correlation was found.

DISCUSSION

One of the most perplexing features of sickle cell anemia is the extreme variability of the hematologic characteristics and severity of its symptomatological components when a large number of patients are analyzed. It has recently become clear that one of the sources of this heterogeneity is the presence of the HbS gene on chromosomes bearing at least three different arrays of linked genes and sequences, which arose and expanded in geographically segregated regions of Africa and generated three β gene cluster haplotypes linked to these HbS genes.[1] The Senegalese haplotype is found in Senegal and surrounding areas of Atlantic West Africa; the Benin haplotype is found in Benin and surrounding areas of Central West Africa and in North Africa and the Mediterranean where its presence has been extended through gene flow; and finally, the Bantu haplotype is found in the Central African Republic and presumably (on the basis of *Hpa*I polymorphism data) in the whole of the Bantu-speaking equatorial and Southern Africa.

To what extent do these different haplotypes linked to HbS generate different hematologic, genetic, and clinical features? Are there three types of sickle cell anemia?

Table 3. Hematologic Parameters in SS Patients with Bantu Haplotype (≥5 Years Old) Divided into Two Subsets by $^G\gamma$ Level

	<38% $^G\gamma$*		>38.1% $^G\gamma$†

†20($\alpha\alpha/\alpha\alpha$), 14($-\alpha/\alpha\alpha$); n = 34.

‡$P < .0000003$.

We have partially answered this question, previously, by studying[4] haplotypically homozygous SS patients bearing the Senegalese and the Beninian haplotypes. That study demonstrated that, indeed, the Senegalese haplotype linked to the HbS was characterized by higher HbF levels, a lower percentage of dense cells, and a high $^G\gamma$ expression in the adult. That their features are genetic in origin is given considerable support by the finding that the same haplotype induces a similar HbF response in thalassemia even though this disease is under different pathophysiological control.[11] In contrast, the Beninian haplotype was characterized[4] by SS patients exhibiting lesser amounts of HbF, a larger proportion of dense cells,[12] and low $^G\gamma$ gene expression. A model that describes the combined effect of α-thalassemia and percent HbF on percent F4 (dense cells) was developed for our New York black population[8] and for the Senegalese and Beninian populations.[4] The relative contribution of α-thalassemia and percent HbF was different for each population as would be anticipated if there were a third factor (haplotype) that also affects dense cell generation.

The characteristics of SS patients bearing the Bantu haplotype have features that distinguish them from the other two haplotypes. First, the mean and mode (Table 2 and Fig 1) of the percentage of HbF is high and similar to the SS patients with Senegalese haplotypes. Nevertheless, the distribution of the values is different: no SS patient with Senegalese haplotype had an HbF level less than 5%, whereas 11% of Bantus had an HbF level between 0% and 5%, although mostly between 2.6% and 5% (Fig 1). The situation is considerably different among the patients bearing the Benin haplotype who exhibit a HbF distribution with a mode between 2.6% and 5% and a very nongaussian distribution with a long tail toward the higher values. Another important feature of the Bantu sickle cell anemia patient is their low percentage of dense cells, again similar to the Senegalese and not exclusively due to higher frequency of α-thalassemia among the Bantu. Although there is a significant correlation between percent F4 or percent ISC and percent HbF in both populations, a lesser proportion of the variability can be explained by the level in the percentage of HbF among the Bantu than in the Senegalese ($r^2 = .53$ v .10). However, if only the non-α-thalassemic Bantu patients are considered, r^2 rises from .10 to .22 with a $P > .02$.

A further characteristic that differentiates the Senegalese from the Bantu is the $^G\gamma$ expression. The Senegalese exhibit a high $^G\gamma$ expression among adults, an infrequent finding among normal individuals who switch from the newborn 70% $^G\gamma$/30% $^A\gamma$ ratio to the adult 40% $^G\gamma$/60% $^A\gamma$ ratio during the first 4 months of life. The Bantu SS have the low $^G\gamma$ expression (Table 1) characteristic of adults.

Although the genetic linkage between HbS and haplotypes and between haplotypes and $^G\gamma$ expression is well established,[1,4,11] no formal linkage analysis of the percentage of HbF and haplotype has yet been possible. Although the statistically significant association between the mean and frequency distribution of the percentage of HbF and haplotype suggests genetic linkage, it is nevertheless already clear that modulating epistatic effects from other genes or factors will result in a not very tight linkage. Family studies, hampered by the absence of the anemia-induced HbF response in parents, will be needed to quantify the linkage.

The next question is whether there is a correlation between percent $^G\gamma$ and percent HbF. Previous studies of American SS patients over the age of 5 have found no significant correlation between these two parameters[13] (although a weak correlation was found in SS patients below this age), and the same is true of the previously studied Beninian SS patients[4] (Fig 2). On the other hand, among SS patients bearing the Bantu haplotype there is a significant correlation ($P <$ .0001) between $^G\gamma$ and HbF that, on further analysis, seems to arise from a cluster of individuals with a low expression of $^G\gamma$ (<38%). This group is little represented among the Senegalese, the Beninians, and the patients analyzed by Huisman et al.[13] The low $^G\gamma$ subset is associated with a low percentage of HbF, whereas the subset with higher $^G\gamma$ expression has a significantly higher percentage of HbF (Table 3). Interestingly, the variance is low in the former and large in the latter. These findings explain why no significant correlation has been found in populations of patients in which the group with low $^G\gamma$ expression is not well represented. In addition, if the data of the Huisman group[13] is divided into less than and more than 38% $^G\gamma$, a significantly lower percentage of HbF is observed for the <38% $^G\gamma$ subset: for patients who are 5 years old or older, the mean is 3.87 ± 3.3 compared with 12.2 ± 5.5 for the >38.1% $^G\gamma$ ($P < .01$).

The low $^G\gamma$ subset exhibits poor correlation between HbF and F4 or ISC, whereas the higher than 38.1% subset exhibits a strong negative correlation ($r = .53$, $P < .005$). This dimorphic population explains the lower correlation of HbF and dense cells in the overall sample.

The heterogeneity in $^G\gamma$ expression among the Bantu and its relation to HbF expression is a significant finding that opens new avenues of investigation. Our working hypothesis is that the subset with lower than 38% $^G\gamma$ corresponds to a distinct chromosome bearing different HbF determinants than the rest of Bantu haplotypes (although not distinguishable by the ten endonuclease-definable polymorphic sites including the *Xmn*I site). Efforts to define these determinants by sequencing are underway in our laboratory.

A complementary explanation is that the enrichment factor (the ratio between F cells and F reticulocytes[14]) might modulate the HbF level, particularly among individuals with a percentage of $^G\gamma$ between 38 and 50. This last effect might be the consequence of the dependence of the enrichment factor on the constitutive HbF expression (percentage of HbF reticulocytes), a possibility supported by the data of Dover et al.[14] These variations also might affect the resulting percentage of HbF more significantly in higher HbF-producing individuals. In addition, the variability of dense cells with respect to HbF level might depend on the distribution function of HbF among HbS-containing cells, a factor that may be genetically determined.

We conclude that the Bantu haplotype results in yet another set of hematologic and genetic characteristics that exhibit a high mean HbF percentage (although with a different distribution than the Senegalese), a low percentage of dense cells (although less determined by the HbF level than among Senegalese), and a low $^G\gamma$ expression (unlike the high $^G\gamma$ expression characteristic of the Senegalese) but with a wide range of the $^G\gamma$ percentage (unlike the distribution among Beninians).

Because patients in the Americas originated from the three geographically segregated but haplotypically homogenous areas of Africa,[15] they can be expected to belong to the three types of sickle cells anemia, but it is further complicated by both non-African admixture and by the presence of a high number of haplotypically heterozygous individuals whose hematologic characteristics have not been defined.

ACKNOWLEDGMENT

The In Vitro Synthesis of Polypeptides for the Platelet Membrane Glycoproteins IIb and IIIa

By Samuel M. Silver, Margaret M. McDonough, Gaston Vilaire, and Joel S. Bennett

The platelet membrane glycoproteins IIb (GpIIb) and GpIIIa form calcium-dependent heterodimers containing binding sites for fibrinogen, von Willebrand factor, and fibronectin. Although GpIIb and GpIIIa are distinct proteins, both GpIIb and GpIIIa are deficient in platelets from individuals with the recessive disorder Glanzmann's thrombasthenia. To gain a better understanding of the genetic basis for GpIIb and GpIIIa synthesis, we studied their synthesis by two human leukemia cell lines, HEL and K562. HEL cells contained complexes of GpIIb and GpIIIa, and K562 cells expressed GpIIIa, but not GpIIb, when stimulated with phorbol-12-myristate-13-acetate (PMA). RNA from HEL cells directed the in vitro synthesis of a 110,000-M_r precursor for GpIIb and a 92,000-M_r precursor for GpIIIa, which indicates that the synthesis of GpIIb and GpIIIa by HEL cells is directed by separate mRNAs. In contrast, RNA from PMA-stimulated K562 cells only directed the synthesis of a 92,000-M_r precursor for GpIIIa. The dissociation of GpIIb and GpIIIa synthesis in K562 cells suggests that GpIIb and GpIIIa may be the products of separate genes.

THE GLYCOPROTEINS IIb and IIIa (GpIIb and GpIIIa)[1] exist as calcium-dependent heterodimer complexes on the surface of unactivated platelets. Following platelet activation, the complexes express binding sites for fibrinogen,[1,2] von Willebrand factor,[3] and fibronectin.[4] GpIIb and GpIIIa are distinct proteins. They differ in subunit structure, have dissimilar tryptic peptide maps, and lack antigenic cross-reactivity.[5-7] Thus, it is not obvious why both glycoproteins are deficient to a similar extent in platelets from individuals with the autosomal recessive disorder Glanzmann's thrombasthenia.[8] To gain a better understanding of the genetics of GpIIb and GpIIIa, in vitro studies of their synthesis will be required. Unfortunately, platelets are not suitable cells for these studies because they retain little protein synthetic capacity. Furthermore, although megakaryocytes synthesize GpIIb and GpIIIa, the number of megakaryocytes that can be isolated is limited by their paucity in bone marrow specimens.[9,10] To overcome these problems we have studied GpIIb and GpIIIa synthesis using cells from two human leukemia cell lines, HEL and K562.[11,12] In this report we have characterized the GpIIb and GpIIIa synthesized by HEL and K562 cells. Furthermore, using RNA isolated from each cell line, we have demonstrated that the synthesis of these proteins is directed by separate species of mRNA, which suggests that GpIIb and GpIIIa are the products of separate genes.

MATERIALS AND METHODS

Preparation of polyclonal antisera against platelet GpIIb and GpIIIa. Polyclonal anti-GpIIb and anti-GpIIIa antisera were prepared by immunizing rabbits with purified human platelet GpIIb and GpIIIa. To purify platelet GpIIb and GpIIIa, outdated human platelets were extracted with 1% Triton X-100 in 0.05 mol/L Tris buffer, pH 7.4, containing 1 mmol/L $CaCl_2$.[13] Affinity chromatography was then performed with the GpIIb/GpIIIa complex-specific monoclonal antibody A_2A_9 immobilized on Sepharose.[14] Retained GpIIb-GpIIIa complexes were eluted with 0.05 mol/L diethylamine, pH 11.5, and precipitated with 6 vol of cold acetone.[14] The eluted GpIIb and GpIIIa were then separated by 0.1% sodium dodecyl sulfate (SDS)-7.5% polyacrylamide gel electrophoresis performed in the absence of a reducing agent.[15] Regions of the gels containing GpIIb and GpIIIa were excised, and the glycoproteins were removed by electroelution. Prior to immunizing rabbits, GpIIb and GpIIIa were reduced with 0.2 mol/L dithiothreitol and alkylated with 0.25 mol/L iodoacetamide. Anti-GpIIb and anti-GpIIIa IgG were prepared from rabbit immune serum by affinity chromatography on protein A-Sepharose (Pharmacia Fine Chemicals, Piscataway, NJ). Prior to use, the IgG were incubated with thrombasthenic platelets and with either purified GpIIb or GpIIIa fixed to Immulon 2 plates (Dynatech Laboratories, Alexandria, VA).

Immunoblotting with anti-GpIIb and anti-GpIIIa IgG. HEL cells (a gift from Dr Thalia Papayannopoulou, University of Washington, Seattle) and K562 cells were grown in RPMI 1640 medium (Flow Laboratories, McLean, VA) containing 10% fetal calf serum. Log growth phase cells were seeded at 0.5 × 10^6/mL. For some experiments, K562 cells were grown in the presence of 10^{-8} mol/L phorbol-12-myristate-13-acetate (PMA) (Sigma Chemical Co, St Louis) because this phorbol ester was reported to induce the expression of platelet antigens by this cell line.[12] Cells were extracted with 0.5% Triton X-100 in 0.05 mol/L Tris buffer, pH 7.4, containing 0.15 mol/L NaCl, 1 mmol/L phenylmethylsulfonyl fluoride, and 1 mmol/L *N*-carbobenzoxy-L-glutamyl-L-tyrosine (buffer A). Aliquots of the extracts containing 150 to 300 μg protein were then electrophoresed on 0.1% SDS-7.5% polyacrylamide slab gels. Disulfide reduction was accomplished with 10% 2-mercaptoethanol. Following electrophoresis, separated proteins were transferred to nitrocelluose paper (Schleicher & Schuell, Inc, Keene, NH). Immunoblotting was performed using a 1/20 dilution of either rabbit anti-GpIIb or anti-GpIIIa IgG and ^{125}I-labeled staphylococcal protein A (Boehringer Mannheim, Indianapolis) as previously described.[16] The labeled immunoblots were dried and exposed to Kodak X-Omat AR photographic film for 24 to 96 hours.

Immunoprecipitation of GpIIb and GpIIIa from HEL and K562 cells. HEL cells, K562 cells, and human platelets were labeled with ^{125}I using lactoperoxidase/H_2O_2 and were extracted with 0.5%

Triton X-100 in buffer A. Fixed staphylococci (Pansorbin, Calbiochem-Behring Corp, La Jolla, CA) were used to collect immune complexes and were prepared by heating at 100°C for ten minutes in 2 mMol/L Tris buffer, pH 7.5 containing 3% SDS and 10% 2-mercaptoethanol and washing five times with 2 mmol/L Tris buffer, pH 7.5, containing 0.1% SDS and 0.1% Triton X-100.[17] Cell solutions were cleared by incubating 100-μL aliquots with 2 μL of nonimmune rabbit serum for 15 minutes at 4°C followed by an incubation with 10 μL of a 10% suspension of staphylococci for 15 minutes at 4°C. Ten to 20 μg of either anti-GpIIb or anti-GpIIIa IgG were then added to the supernatants and the incubations continued at 4°C for 16 hours. Immune complexes were collected by adding 100 μL of a 10% suspension of staphylococci for 1 hour at 4°C. The staphylococci were then washed five times with 2 mmol/L Tris buffer, pH 7.5, containing 0.15 mol/L NaCl, 0.1% SDS, and 0.1% Triton X-100 and were heated at 100°C for five minutes in 0.01 mol/L Tris-HCl buffer, pH 6.8, containing 3% SDS. Immune complexes were electrophoresed on unreduced 0.1% SDS–7.5% polyacrylamide slab gels. The gels were dried and exposed to Kodak X-Omat AR film for one to three days.

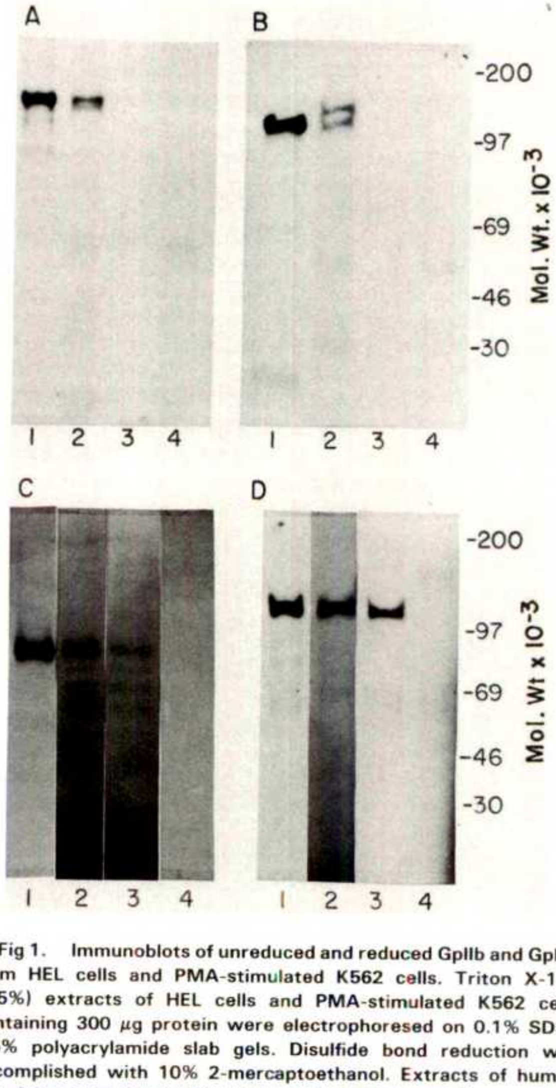

Fig 1. Immunoblots of unreduced and reduced GpIIb and GpIIIa from HEL cells and PMA-stimulated K562 cells. Triton X-100 (0.5%) extracts of HEL cells and PMA-stimulated K562 cells containing 300 μg protein were electrophoresed on 0.1% SDS–7.5% polyacrylamide slab gels. Disulfide bond reduction was accomplished with 10% 2-mercaptoethanol. Extracts of human platelets were prepared in the same manner as positive controls. The separated proteins were electrophoretically transferred from the gels to nitrocellulose paper and were examined by immunoblotting by using rabbit anti-GpIIb and anti-GpIIIa IgG and ^{125}I-labeled staphylococcal protein A. Autoradiograms of the dried blots are shown in the figure. Molecular weights were calculated from the mobility of standard proteins. (A, B) Immunoblots using anti-GpIIb IgG. (C, D) Immunoblots using anti-GpIIIa IgG. (A, C) Immunoblots of unreduced gels. (B, D) Immunoblots of reduced gels: 1, platelets; 2, HEL cells; 3, K562 cells grown in the presence of 10^{-8} mol/L PMA for 48 hours; 4, unstimulated K562 cells.

Detection of platelet GpIIb and GpIIIa antigens on the surface of intact HEL and K562 cells. To detect platelet-specific GpIIb and GpIIIa antigens on the surface of intact HEL and K562 cells, 0.35 × 10^6 cells were incubated with dilutions of a panel of antihuman platelet GpIIb, GpIIIa, and GpIIb-IIIa murine monoclonal antibodies for 30 minutes at 4°C in a buffer consisting of Dulbecco's phosphate-buffered saline (GIBCO, Grand Island, NY) with 0.02% sodium azide and 0.2% bovine serum albumin. After a second incubation with a 1/40 dilution of affinity-purified fluorescein isothiocyanate–conjugated goat (Fab')$_2$ antimurine immunogobulin (Tago Diagnostics, Burlingame, CA) for 30 minutes at 4°C, the cells were examined in a fluorescent cell analyzer (Spectrum III, Ortho Diagnostics, Westwood, MA). Antibody binding was considered positive if the number of fluorescent cells exceeded the number seen with the negative control antibody P3 × 63. The monoclonal anti-GpIIb antibody Tab was a gift from Dr Rodger McEver.[18] The monoclonal antibody B1B5 was produced by immunizing mice with purified human platelet GpIIb. It binds only to platelet GpIIb on immunoblots of human platelet membranes.

In vitro translation of GpIIb and GpIIIa. GpIIb and GpIIIa precursors were translated in vitro using RNA purified from HEL and K562 cells by the method of Deeley et al.[19] For some experiments mRNA was isolated from the total cellular RNA by chromatography on oligo-dT cellulose (Bethesda Research Laboratories, Gaithersburg, MD). RNA translations were performed at 37°C for 60 minutes in the presence of dithiothreitol by using a rabbit reticulocyte lysate in vitro translation system (New England Nuclear, Boston). Translation of HEL RNA was performed in the presence of [^{35}S]methionine (New England Nuclear). GpIIb and GpIIIa precursors were immunoprecipitated from the translation mixture with polyclonal anti-GpIIb or anti-GPIIa IgG and identified by SDS–polyacrylamide gel electrophoresis performed under reducing conditions. The specificity of the immunoprecipitations was tested by preincubating the IgG with 5 to 10 μg of either purified platelet GpIIb or GpIIIa. Following electrophoresis, the gels were prepared for fluorography (Autofluor, National Diagnostics, Somerville, NJ), dried, and exposed to Kodak X-Omat AR film at −70°C for one to three days. RNA purified from K562 cells was translated in vitro in the presence of unlabeled methionine. The translation products were dissolved in SDS and examined by immunoblotting. Monospecific polyclonal rabbit anti-GpIIb and anti-GpIIIa antisera and ^{125}I-labeled staphylococcal protein A were used for these blots.

RESULTS

Characterization of HEL and K562 GpIIb and GpIIIa. To detect HEL GpIIb and GpIIIa, cell extracts were prepared with Triton X-100, electrophoresed on SDS–polyacrylamide gels under nonreducing and reducing conditions, and examined by immunoblotting with polyclonal anti-GpIIb and anti-GpIIIa IgG (Fig 1). We found that HEL cells contained polypeptides reacting with both anti-GpIIb and anti-GpIIIa IgG. Under nonreducing conditions, anti-GpIIIa IgG reacted with a 95,000-M_r polypeptide. Following reduction, the apparent M_r of this polypeptide increased to 116,000. This increase in apparent M_r following reduction is similar to the behavior of platelet GpIIIa upon reduction and suggests that HEL GpIIIa, like platelet GpIIIa, is a single-chain polypeptide with multiple intrachain disulfide bonds.[7] Anti-GpIIb IgG under nonreducing conditions reacted with a 140,000-M_r polypeptide. However, under reducing conditions, it reacted with two polypeptides, the 140,000-M_r polypeptide and a second polypeptide with an M_r of 125,000. Platelet GpIIb is a disulfide-linked two-chain molecule containing a 125,000-M_r α chain and a 23,000 M_r β chain.[7] Bray et al recently reported that HEL GpIIb is synthesized as a single-chain precursor that is processed posttranslation into α and β chains.[20] The M_r of the polypeptides recognized by our anti-GpIIb IgG correspond to those of platelet GpIIb and GpIIbα, respectively. This suggests that HEL cells contain two pools of GpIIb molecules, one containing disulfide-linked α and β chains and a second that did not undergo cleavage into α and β chains.

We also performed immunoblotting with extracts of unstimulated and PMA-stimulated K562 cells (Fig 1). Anti-GpIIIa IgG did not react with any polypeptides on the immunoblots of the unstimulated cells but did react with a 95,000-M_r polypeptide after the cells had been incubated with 10^{-8} mol/L PMA for at least 12 hours. Furthermore, like HEL and platelet GpIIIa, the molecular weight of this polypeptide increased to 116,000 following disulfide reduction. However, in contrast to HEL cells and platelets, anti-GpIIb IgG did not react with any polypeptides on immunoblots of extracts of either unstimulated K562 cells or of K562 cells stimulated with PMA for as long as 72 hours.

To determine whether HEL GpIIb and GpIIIa and K562 exist in heterodimer complexes, we performed immunoprecipitations using Triton X-100 extracts of ^{125}I-labeled cells and the polyclonal anti-GpIIb and anti-GpIIIa IgG. Immunoprecipitations also were performed with ^{125}I-labeled human platelets. As seen in Fig 2, anti-GpIIb and anti-GpIIIa IgG each immunoprecipitated both components of the GpIIb-GpIIIa heterodimer from the platelet extracts.[13] Similarly, anti-GpIIb IgG immunoprecipitated both GpIIb and GpIIIa from the HEL cell extracts. This result indicates that at least a portion of the HEL GpIIb and GpIIIa exists in heterodimer complexes. Due to partial reduction of the GpIIb during the immunoprecipitation, a polypeptide corresponding to GpIIbα was also present in this immunoprecipitate. Anti-GpIIIa IgG also immunoprecipitated GpIIb and GpIIIa from the dissolved HEL cells. However, the predominant polypeptide in this immunoprecipitate was GpIIIa. The reason for the difference in the composition of the HEL immunoprecipitates depending on whether anti-GpIIb and anti-GpIIIa IgG was used is not clear because the immunoprecipitations were performed under identical conditions but a similar difference in the composition of the immunoprecipitates was seen in the platelet controls.

As we expected from the K562 immunoblots, anti-GpIIIa immunoprecipitated a GpIIIa analogue from extracts of PMA-stimulated K562 cells but not from extracts of unstimulated cells. However, we did not detect another polypeptide complexed with GpIIIa in these immunoprecipitates, nor was a GpIIb analogue present in immunoprecipitates using anti-GpIIb IgG. These data confirm that PMA-stimulated K562 cells express a GpIIIa-like protein and do not express a protein antigenically similar to platelet GpIIb. They also suggest that GpIIIa does not exist in a complex in PMA-stimulated K562 cells.

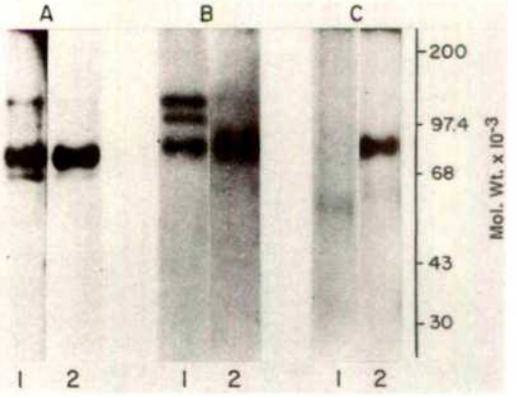

Fig 2. Identification of GpIIb and GpIIIa antigens from HEL and K562 cells by immunoprecipitation. Immunoprecipitations were performed by using ^{125}I-labeled HEL cells, K562 cells, and human platelets dissolved with 0.5% Triton X-100 in a buffer containing 0.05 mol/L Tris, 0.15 mol/L NaCl, 1 mmol/L phenylmethylsulfonyl fluoride, and 1 mmol/L *N*-carbobenzoxy-L-glutamyl-L-tyrosine, pH 7.4, and either monospecific rabbit anti-GpIIb or anti-GpIIIa IgG. Immune complexes were collected with fixed staphylococci and were examined on unreduced 0.1% SDS–7.5% polyacrylamide slab gels. Following electrophoresis, the gels were dried and exposed to Kodak X-omat AR film for one to three days. Molecular weights were calculated from the mobility of concurrently run standard proteins. (A) Human platelets. (B) HEL cells. (C) K562 cells grown in the presence of 10^{-8} mmol/L PMA for 48 hours: 1, immunoprecipitation using anti-GpIIb IgG; 2, immunoprecipitation using anti-GpIIIa IgG.

Last, to compare the antigenic reactivity of HEL and K562 GpIIb and GpIIIa antigens with their platelet counterparts, we incubated cells from each line with a panel of murine antihuman platelet GpIIb and GpIIIa monoclonal antibodies. Although these antibodies react readily with platelets, they do not react with lymphocytes, monocytes, or neutrophils (data not shown). The cells were then incubated with fluorescein-conjugated antimurine IgG F(ab')$_2$ and examined with a fluorescent cell analyzer. The majority of HEL cells exhibited fluorescence after incubation with monoclonal antibodies against human platelet GpIIb, GpIIIa, and the GpIIb/IIIa complex (Table 1). In contrast, K562 cells only exhibited background fluorescence when incubated with the same antibodies. However, after these cells were exposed to 10^{-8} mol/L PMA, the majority exhibited fluorescence after incubation with the anti-GpIIIa monoclonal antibody A6. A small increment in fluorescence was also seen when the PMA-stimulated K562 cells were incubated with monoclonals against GpIIb and the GpIIb/IIIa complex. However, this increment was the result of an increase in background fluorescence that followed cell stimulation with PMA, consistent with our inability to detect GpIIb synthesis in K562 cells by immunoblotting or immunoprecipitation.

In vitro synthesis of GpIIb and GpIIIa by using RNA from HEL cells. Purified HEL RNA was translated in vitro by using a rabbit reticulocyte lysate translation system in the presence of [^{35}S]methionine. Newly synthesized poly-

K562 cells were grown for 48 hours in the presence or absence of 10^{-8} mol/L PMA. These cells and HEL cells were incubated for 30 minutes at 4 °C with a panel of antihuman platelet monoclonal antibodies as described under Methods. The cells were then washed and incubated for 30 minutes at 4 °C with a 1/40 dilution of affinity-purified fluorescein isothiocyanate-conjugated goat $(Fab')_2$ antimurine IgG before they were studied in a fluorescence cell analyzer. Fluorescence thresholds for positivity were adjusted by using the antibody P3x63 as a negative control. Percent binding indicates the percentage of the analyzed cells whose fluorescence was greater than the threshold. The number in brackets indicates the number of experiments. The data are mean values.

peptides containing GpIIb and GpIIIa antigens were identified by immunoprecipitation using monospecific rabbit IgG. Following the translation of 6.2 μg of HEL RNA, anti-GpIIb IgG immunoprecipitated a single ^{35}S-labeled polypeptide with an M_r of approximately 110,000 (Fig 3). The immunoprecipitation was specific for a GpIIb precursor because it was inhibited by preincubating the IgG with purified platelet GpIIb. Likewise, following translation of 25 μg of HEL RNA, anti-GpIIIa IgG immunoprecipitated a labeled polypeptide with an M_r of approximately 92,000. Preincubation of the anti-GpIIIa IgG with purified platelet GpIIIa also inhibited this immunoprecipitation. Thus, HEL cell RNA directed the synthesis of distinct precursors for GpIIb and GpIIIa. Because no processing of polypeptides occurs in our in vitro translation system and because in eukaryotes each species of cellular mRNA codes for a single polypeptide, our results indicate that the synthesis of GpIIb and GpIIIa is directed by separate mRNAs.

In vitro synthesis of GpIIIa by using RNA from K562 cells. The K562 RNA in vitro translation products were examined by immunoblotting by using rabbit polyclonal anti-GpIIb and anti-GpIIIa antisera and ^{125}I-labeled staphylococcal protein A (Fig 4). Anti-GpIIIa antiserum identified a single 92,000-M_r polypeptide whose synthesis was directed by RNA from PMA-stimulated cells. The mobility of this polypeptide was the same as the HEL polypeptide immunoprecipitated with anti-GpIIIa IgG. A faint band with the same mobility was also seen in the translation directed by RNA from non–PMA-stimulated cells, but no bands were present when water or globin mRNA was substituted for K562 RNA. Likewise, no polypeptides reacting with anti-GpIIb antiserum were detected in these translations (data not shown). Thus, PMA-stimulated K562 cells express a gene for GpIIIa. If the gene for GpIIb is also expressed, then its level of expression is below our limits of detection.

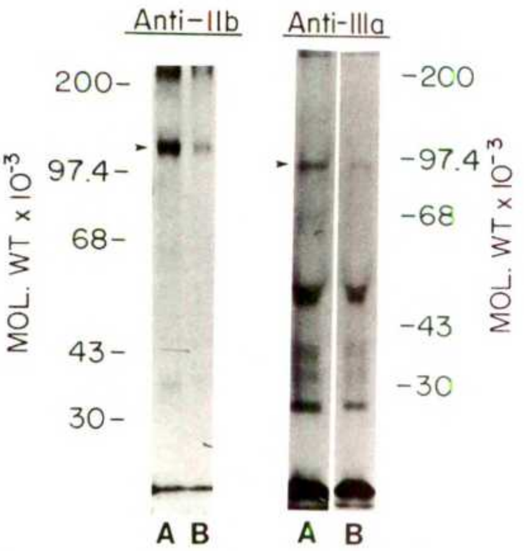

Fig 3. In vitro translation of GpIIb and GpIIIa using RNA from HEL cells. HEL cell RNA was purified and translated in vitro in the presence of [^{35}S]methionine by using a rabbit reticulocyte lysate translation system. Newly synthesized GpIIb and GpIIIa were identified by immunoprecipitation by using rabbit anti-IIb and anti-IIIa IgG. The specificity of the immunoprecipitations was tested by preincubating the IgG with 5 to 10 μg of either purified platelet GpIIb or GpIIIa. In the experiment shown, translation of 6.2 μg of total cell RNA was required to detect GpIIb, whereas the detection of GpIIIa required the translation of 25 μg of RNA. This figure is an autofluorogram of a 0.1% SDS–7.5% polyacrylamide gel of the immunoprecipitates. (A) Immunoprecipitation in the absence of purified platelet protein. (B) Immunoprecipitation in the presence of purified platelet protein.

DISCUSSION

The platelet membrane glycoproteins IIb and IIIa form a heterodimer complex that is of critical important for normal platelet function because it is the platelet surface structure that mediates platelet aggregation.[14] Evidence is also accumulating that platelet GpIIb and GpIIIa are members of a family of adhesive protein receptors. Proteins antigenically and structurally related to platelet GpIIb and GpIIIa have been found on endothelial cells,[21,22] and complexes similar to GpIIb-IIIa are present on myeloid and lymphoid cells.[23] For example, the OKM1 antigen found on myeloid cells and the LFA-1 antigen found on lymphoid and myeloid cells are both noncovalent heterodimers containing a common 94,000-M_r glycoprotein complexed with either a 155,000- or a 177,000-M_r glycoprotein.[23] Both OKM1 and LFA-1 are involved in the adherence of effector cells to target cells.[24,25] Recently, Cosgrove et al isolated a single clone from a human genomic library that when expressed produced antigens found on the large subunits of OKM1 and LFA-1 and on GpIIb.[26] Although the large subunits of OKM1, LFA-1, and GpIIb-IIIa are distinct glycoproteins, these data suggest that the proteins contain common amino acid sequences that have been conserved for cellular adhesive functions. Burns et al have directly implicated the GpIIb-IIIa complex in leukocyte adhesion.[27] They produced a monoclonal antibody against lymphocytes that not only modified leukocyte function but also inhibited platelet aggregation and immunopre-

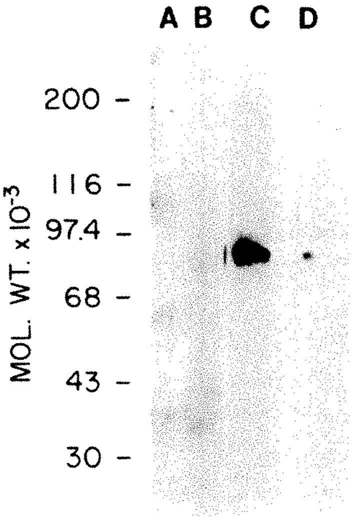

Fig 4. In vitro translation of GpIIIa using RNA from K562 cells. RNA was isolated from K562 cells and translated in vitro as described in Fig 3 except that the translation was performed with unlabeled methionine. The translation products were subjected to SDS–polyacrylamide gel electrophoresis as described in Fig 3 and examined by immunoblotting as described in Fig 1. Monospecific rabbit anti-GpIIIa IgG and ^{125}I-labeled staphylococcal protein A were used in these blots. (A, B) control translations in which water and globin mRNA were substituted for K562 RNA, respectively. (C) Translation directed by RNA from K562 cells exposed to PMA for 48 hours. cipitated the platelet GpIIb-IIIa complex. On the other hand, it is unlikely that there is complete identity between platelet GpIIb and GpIIIa and their leukocyte counterparts because none of our panel of anti-GpIIb and anti-GpIIIa monoclonal antibodies reacts with lymphocytes, monocytes, or neutrophils (data not shown).

Reports that the function of several adhesive protein receptors can be inhibited by peptides containing the amino acid sequence Arg-Gly-Asp-Ser strengthens the concept for a family of adhesion protein receptors.[28] These receptors include the platelet GpIIb-IIIa complex[29-31] and the vitronectin and fibronectin receptors found on fibroblasts, MG-63 osteosarcoma cells, and human placenta.[32,33] Moreover, the vitronectin receptor is a heterodimer whose subunits behave like GpIIb-IIIa on unreduced and reduced SDS-gels.[34] In contrast, the mammalian fibronectin receptor appears as a single 140,000-M_r glycoprotein on reduced gels and as a 140,000/120,000-M_r heterodimer on unreduced gels.[32] In addition, although platelet GpIIb-IIIa appears to be capable of interacting with fibrinogen, fibronectin, and vitronectin, the vitronectin and fibronectin receptors interact solely with their respective ligands, which suggests that important structural difference may exist among the members of the adhesive protein receptor family.[34]

In order to examine the possibility of homology between platelet GpIIb-IIIa and adhesive protein receptors on other cells and to determine whether the synthesis of GpIIb and GpIIIa is under coordinate control, we have searched for cells containing GpIIb and GpIIIa other than megakaryocytes. Although megakaryocytes would seem to be the appropriate cells for our studies, their paucity in bone marrow specimens precludes their use. In confirmation of previous reports[11,12] we found the antigens for several antihuman platelet GpIIb and GpIIIa monoclonal antibodies on HEL cells and an antigen for platelet GpIIIa, but not for platelet GpIIb, on PMA-treated K562 cells. In addition, using polyclonal antihuman platelet GpIIb and GpIIIa IgG, we found that the structures containing these antigens were similar in molecular weight and subunit composition to the corresponding platelet proteins. Thus, HEL cells and PMA-treated K562 cells appear to represent readily available resources for study of GpIIb and GpIIIa synthesis.

As a first step in our studies, we isolated RNA from the HEL cells and from unstimulated and PMA-stimulated K562 cells and translated the RNA in vitro. HEL RNA directed the synthesis of distinct precursors for both GpIIb and GpIIIa, which indicates that the synthesis of each is directed by separate species of mRNA. Thus, GpIIb and GpIIIa do not arise from the posttranslation cleavage of a common precursor. Bray et al have also reported that GpIIb and GpIIIa synthesis by HEL cells is directed by separate mRNAs.[20] In addition, their results suggest that GpIIb and GpIIIa are processed before delivery to the plasma membrane. Confirming their results, we found that the apparent molecular weights of the HEL GpIIb and GpIIIa precursors translated in vitro are consistent with the expected molecular weights of the reduced, nonglycosylated platelet species. Human platelet GPIIb and GPIIIa contain 14% and 16% carbohydrate, respectively.[6] Thus, the estimated molecular weight of nonglycosylated platelet GPIIb containing both α and β chains is 116,000,[7] close to the value for the HEL GPIIb precursor we translated in vitro. A similar estimate for reduced, nonglycosylated platelet GpIIIa is 91,000, again close to the molecular weight of the HEL GpIIIa precursor.

RNA from PMA-stimulated K562 cells directed the synthesis for a GpIIIa precursor that was very similar in size and antigenicity to the HEL GpIIIa precursor. On the other hand, in spite of data that most adhesive protein receptors exist as heterodimers, we did not detect a protein containing GpIIb antigens on PMA-stimulated K562 cells, nor could we translate a GpIIb precursor in vitro using K562 RNA. It is possible that K562 cells produce a protein antigenically unrelated to GpIIb that forms a heterodimer with GpIIIa. However, if such a protein is present it would seem to be substantially different from both platelet and HEL GpIIb.

The simplest explanation for the presence of separate mRNAs for GpIIb and GpIIIa in HEL cells is that each glycoprotein is coded by a separate gene. The dissociation of GpIIb from GpIIIa expression in PMA-stimulated K562 cells is consistent with this explanation. Consequently, it may be necessary to postulate either linked abnormalities in the transcription of the genes for GpIIb and GpIIIa or linked abnormalities in the postsynthetic processing of the GpIIb and GpIIIa precursors to explain the glycoprotein abnormalities in thrombasthenia. Alternative splicing of a single immature mRNA[35] or the presence of several initiation codons within a single cellular mRNA could explain our results and the observations in thrombasthenia. However, the absence of any structural or antigenic relationship between

GpIIb and GpIIIa makes the former possibility unlikely, and the latter situation has only been rarely observed in eukaryotes.[36] Because GpIIIa seems to exist in the K562 cell membrane with little or no GpIIb, it appears that GpIIIa synthesis does not require concominant synthesis of GpIIb, and it seems unlikely that an abnormality in GpIIb synthesis or processing alone could account for thrombasthenia. Our results do not preclude a primary abnormality in GpIIIa synthesis as the explanation for thrombasthenia. However, a thrombasthenic whose platelets have a GpIIb-IIIa pattern similar to that of PMA-stimulated K562 cells has not been described. Direct examination of the genes coding for GpIIb and GpIIIa will be necessary to explain the protein abnormalities in thrombasthenia.

ACKNOWLEDGMENT

We wish to thank Dr James A. Hoxie for help with the use of the fluorescence cell analyzer and Dr Stephen A. Liebhaber for his review of the manuscript.

Immunochemical Characterization of Fibrinogen, Fibrin I, and Fibrin II in Human Thrombi and Atherosclerotic Lesions

By Alessandra Bini, John Fenoglio Jr, Joan Sobel, John Owen, Marcela Fejgl, and Karen L. Kaplan

Arterial thrombi and atherosclerotic lesions were analyzed immunochemically and examined histologically. The extent of in vivo proteolytic cleavage of the amino-terminal end of fibrinogen by thrombin and plasmin was determined and quantitated by specific radioimmunoassays. The samples were treated with cyanogen bromide (CNBr), and the total amount of fibrinogen and fibrin-derived protein was determined as NDSK, the NH_2-terminal disulfide knot of fibrinogen. Thrombin-releasable fibrinopeptides A and B were used to quantitate fibrinogen and fibrin I. Previous plasmin cleavage of the $B\beta$ chain was inferred from the amount of $B\beta$ 1-42 and $B\beta$15-42 in undigested NDSK. The results obtained in both acute and organized thrombi indicate that ~60% of the total protein (as determined by amino acid analysis) was fibrinogen-derived and that 70% to 80% of the fibrinogen-derived material was fibrin II. These findings support the hypothesis that fibrin II as distinct from fibrin I is the predominant component in a thrombus. In samples from normal and atherosclerotic aortas, fibrinogen-derived protein comprised <10% of the total protein. Samples from grossly normal aortas contained only fibrinogen and fibrin I. Fibrinogen concentration decreased and fibrin II concentration increased with increasing severity of the lesions, suggesting that increased fibrin II formation is associated with progression of atheromas.

© 1987 by Grune & Stratton, Inc.

SEVERAL in vitro studies have defined the biochemical structure of fibrin in vitro.[1-4] Little information is available on the composition of human thrombi and atherosclerotic plaques with respect to the content of fibrinogen and resulting fibrin products.

Previous studies on thrombi recovered from patients have been devoted to the carboxy-terminal end of the fibrinogen molecule and have shown fibrin with a high degree of α and γ chain crosslinking.[5,6] Recently, Francis and colleagues[7] demonstrated that the degree of fibrin degradation in thrombi increases progressively with the age of the thrombus and it is more prominent in the deeper layers of chronic thrombi.

The association between thrombus formation and atherosclerotic lesions has long been recognized.[8,9] The presence of fibrinogen and fibrin-related antigens in normal aortas and atherosclerotic plaques has been shown by immunofluorescence and electron microscopy by several investigators.[10-12] Smith and colleagues[13] documented that fibrinogen and fibrin in soft gelatinous human aortic intimal thickenings and cholesterol-rich advanced plaques were, respectively, four and ten times more concentrated than in normal vessels.

Shainoff and Page[14] reported that atherosclerotic plaques contained crosslinked fibrinogen, based on their estimates of fibrinopeptide content and on insolubility in 5 mol/L of urea. In normal aortas and in aortas with atherosclerotic lesions, York and Benjamin[15] found a correlation between the content of fragment D antigen and the severity of the atherosclerotic lesion. No correlation was found with the fibrinogen content of plaques.

Nossel postulated that thrombi should consist mainly of fibrin II*[16] and, in a study of postcraniotomy venous thrombosis,[17] the patients who developed venous thrombosis showed evidence of an imbalance of thrombin and plasmin action that would favor fibrin II formation.

We therefore studied the biochemical composition of the amino-terminal ends of fibrinogen and fibrin in thrombi and atherosclerotic lesions with respect to proteolysis by thrombin and plasmin. Using specific radioimmunoassays, we determined the relative amounts of fibrinogen, fibrin I, fibrin II, and fragment X,[18-22] and compared the data obtained on thrombi with results in normal and atherosclerotic arterial intima.

MATERIALS AND METHODS

Preparation of fibrin in vitro. Platelet-poor plasma was prepared from blood collected into 1/10 vol of an anticoagulant solution consisting of 3.8% trisodium citrate, 100 KIU/mL of aprotinin (Trasylol, Mobay Chemical, FBA, New York), 10 mg/mL soybean trypsin inhibitor (Worthington Biochemical, Freehold, NJ), with or without 80 U/mL of heparin (Heparin sodium, Hynson Westcott and Dunning, Baltimore), and separated by centrifugation for 20 minutes at 1,700 g at 4°C in a Sorvall RC-2 centrifuge (Newton, CN).

*Definition of terms: fibrin I, formed from fibrinogen by cleavage of $A\alpha$16-17; fibrin II, formed from fibrinogen by cleavage of both $A\alpha$16-17 and $B\beta$14-15; NDSK, amino terminal CNBr fragment of fibrinogen; fragment X, formed by plasmin cleavage of the $B\beta$42-43 bond and α-chain bonds of fibrinogen, fibrin I, or fibrin II (includes fragments Y and E as calculated in this study).

Fibrinogen concentration was measured in citrated plasma as described by Ellis and Stransky[23] and by the clot weight method.[24] Plasma obtained from the heparin-containing anticoagulant mixture was clotted overnight at 37°C with batroxobin 1 mg/mL of plasma (Reptilase-R, Abbott Laboratories, North Chicago). Crosslinked fibrin was prepared by adding 1.0 National Institutes of Health (NIH) U of human α-thrombin (3.7×10^3 NIH U/mg) (prepared by Dr J. Fenton and kindly given to us by Dr G. Murano, Bethesda, MD) and 10 μL of a 2.5 mol/L of calcium chloride solution per milliliter of citrated plasma (final concentration 0.025 mol/L of $CaCl_2$), followed by overnight incubation at 37°C. The clots were removed by winding them on a wooden stick; they were rinsed three times for 15 minutes in distilled water, cut longitudinally with a scalpel, stirred for 1 hour in 70% vol/vol of formic acid, and incubated with 300-fold molar excess cyanogen bromide (CNBr),[20-23] for 20 to 24 hours with continuous stirring. The CNBr-treated clots were then diluted 1:11 with distilled water, lyophilized twice, resuspended in 10% NH_4OH (vol/vol) containing 0.01% Tween 20 (vol/vol), and the pH was adjusted to 8 to 8.5 with HCl. Samples were stored at −70°C until assayed.

Sample collection. Thrombi and tissue samples were collected at surgery and at autopsy under a protocol approved by the Institutional Review Board of the Columbia Presbyterian Medical Center. Specimens collected at surgery were placed, immediately on excision, into sterile 50-mL tubes filled with 0.1 mol/L of NaCl, 0.05 mol/L of Tris pH 7.4 containing 100 KIU/mL of aprotinin and 1.0 mmol/L of benzamidine (Benzamidine hydrochloride hydrate, Aldrich Chemical, Milwaukee). They were rinsed in three changes of the same buffer within 2 hours of resection. Samples collected at autopsy 6 to 24 hours postmortem were rinsed carefully in the same buffer. Aortas were incised with a scalpel, and the intima was directly separated from the media and the adventitia. The samples were then divided into grossly homogenous parts, and areas of atherosclerotic aortas were collected with paired normal adjacent areas. Each specimen was individually placed in preweighed siliconized glass vials and frozen and stored at −70°C until processed. Prior to freezing, a portion of each sample was cut and fixed in 10% neutral buffered formaldehyde for histologic examination.

The specimens for histology were paraffin embedded, and 8-μm sections were cut from the blocks and stained with hematoxylin-phloxine-saffran and Masson's trichrome. The stain allows distinction between cells, nuclei, "fibrin," and collagen. The samples were classified as acute or organized thrombi or fibrous, fatty, or complicated plaques according to standard histological criteria (Table 1).

Definitions: Acute thrombus, fibrin clot with discernible lines of Zahn; organizing thrombus, partial replacement of fibrin clot by granulation tissue; organized thrombus, total replacement of fibrin clot by maturing granulation tissue; fibrous plaque, focal intimal accumulation of collagen and "fibroblasts"; fatty plaque, focal intimal accumulation of "foam cells," collagen, and cholesterol crystals; complicated plaque, focal accumulation of foam cells, collagen, and cholesterol crystals extending into the media and associated with calcification.

Sample processing. The tissue samples were freeze-dried in siliconized glass vials and dry-weighed. They were then homogenized in distilled water (10 to 100 mg sample per milliliter of distilled water). If the dry weight was >100 mg, samples were initially roughly homogenized on a melting ice bath with a Polytron (Brinkmann Instruments, Westbury, NY). All samples were finely homogenized at 4°C in a glass homogenizer (Arthur H. Thomas Scientific Apparatus, Philadelphia), kindly made available by Dr S. DiMauro, Department of Neurology, Columbia University. The homogenate was then diluted 1:5 with 90% formic acid and treated with cyanogen bromide as described above. The amount of CNBr added to the tissue samples was five times the dry weight of the sample. Amino acid analysis performed in a preliminary experiment demonstrated that ~50% of the dry weight was protein. This amount of CNBr corresponds to the 300-fold molar excess used for CNBr digestion of fibrin prepared in vitro.

The precipitates present in two samples were extracted a second time with formic acid and CNBr to determine whether residual NDSK antigen was present. The results are shown in Table 2. NDSK antigen was assayed on the initial extract and on the extract from the repeated CNBr treatment of the precipitate that remained after the first extraction. The recovery of fibrinogen-related material in the first extract was 95% from the intima sample and >99% from the organized thrombus. Therefore, all samples in which a precipitate was present after the first extraction were centrifuged at 12,300 g for 30 minutes, and assays for fibrinogen-related antigens were performed on the supernate.

Radioimmunoassays. NDSK, native fibrinopeptide A (FPA) and fibrinopeptide B (FPB), and Bβ 1-42 were prepared as previously described.[2,29-31] Tyrosinated FPA was from Schwarz/Mann, Becton Dickinson, Orangeburg, NY. Tyrosinated FPB was prepared by G. Wilner.[2] Antiserum to NDSK was lot QT8[29]; to FPA it was lot R2,[30,32,33] to FPB it was lot R28,[34] and to Bβ1-42 it was lot 142-3.[31] The Bβ15-42 assay kit was purchased from IMCO (MICO USA, New York).

All fragments were labeled by the method of Hunter and Greenwood.[35] Sodium iodide -^{125}I (1 to 2 mCi) was obtained from New England Nuclear (Boston). After iodination, NDSK was passed over Sephadex G-100, and the other peptides and fragments were passed over Sephadex G-10 (Pharmacia Fine Chemicals, Piscataway, NJ). NDSK was assayed with a slightly different technique from that previously described.[29] The test was performed in 12 × 75-mm polypropylene tubes (Sarstedt, Princeton, NJ). Both tracer and anti-NDSK antibody were diluted in 0.15 mol/L of Tris-NaCl pH 8.5 containing 1% bovine serum albumin (wt/vol) (Pentex Fraction V, lot 19, Miles Laboratories, Elkhart, IN), 1/50 (vol/vol) final concentration normal rabbit serum (Rabbit Whole Serum lot 23008, Cappel Scientific, Malvern, PA) and 0.01% NaN_3 (wt/vol). After overnight incubation at 4°C, goat anti-rabbit IgG antiserum (lot 0050, Miles Scientific, Naperville, IL) was added at 1/10 dilution in Tris-NaCl containing 1% bovine serum albumin (BSA) and 2% polyethylene glycol (wt/vol) (PEG 8000, J.T. Baker Chemical, Phillipsburg, NJ). The samples were incubated for 2 hours at 4°C, and the bound antigen was separated by centrifugation, as previously described. Radioimmunoassays for FPA,[30] FPB,[2] Bβ1-42,[31] and Bβ15-42[36] were performed by our published double-antibody technique, substituting first antibody, tracer, standard, and second antibody as appropriate.[37]

The assay buffer for all of these assays is 0.15 mol/L of Tris-NaCl pH 8.0 containing 1.0% PEG 8000, heparin (0.7 U/mL), 0.01% Tween 20, and 0.01% NaN_3. The bound antigen was separated by centrifugation at 1,700 g for 20 minutes, the supernate was aspirated, and the precipitate was counted for 1 minute with an LKB 1270 Rackgamma II, (LKB Instruments, Rockville, MD).

Calculation of fibrinogen-derived material. The radioimmunoassays applied to identify and quantitate the fibrinogen NH_2-terminal antigens present in the CNBr-treated samples are shown in Table 3.

The radioimmunoassay (RIA) for NDSK detects fibrinogen and fibrin quantitatively. Experiments were made to characterize the anti-NDSK antiserum used. Comparable immunoreactivity was observed in the following preparations: NDSK, thrombin-treated NDSK,[38] plasmin-treated NDSK, reduced and alkylated NDSK, and CNBr-degraded fibrinogen derived from early (5 to 20 minutes), and late (60 minutes and overnight) plasmin digests. Non-CNBr–treated fragment E is 30 times less reactive than the other preparations.[29] The NDSK assay accurately measured all fibrinogen and fibrin-related material in the samples, however, since all samples were treated with CNBr before assay.

The RIA for fibrinopeptide A measures only the free peptide.[30,32,33] Thus, the fibrinopeptide A released by thrombin treatment of the samples provides a measure of residual fibrinogen. The FPB RIA similarly measures only the free peptide. Fibrinopeptide B released by thrombin treatment thus gives the sum of the fibrinogen and fibrin I in the samples examined.

In the Bβ1-42 RIA, the antibody used requires an intact Bβ14-15 peptide bond, and it recognizes the Bβ1-42 fragment either as a free peptide or within fibrinogen or NDSK. It is therefore a measure of both fibrinogen and fibrin I, but not of fibrin II or fragment X, which lack FPB or Bβ1-42, respectively.

The antibody used in the Bβ15-42 RIA crossreacts completely with all the Bβ15-42–containing fragments derived from CNBr treatment. Therefore, Bβ15-42 provides a measure of fibrinogen, fibrin I, and fibrin II, but not of fragment X.

The total fibrinogen-derived material and the proportions of fibrinogen, fibrin I, fibrin II, and fragment X in samples can be calculated from these data using the formulae shown in Table 4.

The molar amount of NDSK represents fibrinogen plus fibrin I, fibrin II, and fragment X. The percentage of intact fibrinogen is calculated as the difference in FPA immunoreactivity before and after thrombin treatment. Because measurement of either releasable FPB or of Bβ1-42 provides an index of fibrin I, the mean of these two

Table 4. Summary of Calculations of Percentage of Fibrinogen, Fibrin I, and Fibrin II in NDSK

Fibrinogen = FPA*/2 NDSK† × 100
Fibrin I = [(FPB + Bβ1-42)/2 − FPA]/2 NDSK × 100
Fibrin II = (Bβ15-42 − [(FPB + Bβ1-42)/2])/2 NDSK × 100
Fragment X = (2 NDSK/2 NDSK × 100) − (Bβ15-42/2 NDSK × 100)

Abbreviations as in Table 2.

*FPA and FPB represent the total amount of fibrinopeptides measured after incubation with thrombin, from which the value obtained before thrombin treatment was subtracted.

†NDSK measured by radioimmunoassay represents 100% of the fibrinogen-related material in each sample. Because 1 mol of NDSK contains 2 mol of each of the fibrinopeptides, the amount of NDSK is multiplied by a factor of 2 in the above formulae.

measurements minus the previously calculated value for intact fibrinogen is used to calculate the percentage of fibrin I more accurately than does a measurement based only on fibrinopeptide B release from NDSK.[3,4] Fibrin II lacks both fibrinopeptides but contains the Bβ15-42 fragment. It is therefore calculated by subtracting the molar amount of Bβ1-14 containing molecules from the total Bβ15-42 immunoreactivity.

Because fragment X arises by cleavage of the Bβ42-43 bond, with loss of Bβ15-42, the percentage of fragment X in the samples can be calculated by subtracting the percentage of Bβ15-42 from the percentage of total NDSK.

Amino acid analysis. The analyses were performed with a Beckman automatic amino acid analyzer model 121 MB (Beckman Instruments, Fullerton, CA), following acid hydrolysis under a vacuum (6 N HCl for 24 hours at 110°C). All chemicals were of reagent grade and were purchased from Fisher Scientific, Springfield, NJ.

Statistical analysis. The statistical significance of variation of the content of fibrinopeptides in the thrombi and atherosclerotic plaques was tested by one-way analysis of variance. In the analysis of variance, a variance is computed from the within-group variation, and the statistical significance of the between-group variation is tested by comparing the ratio of the between-group to within-group variations to the appropriate F value in a table. The Bonferroni procedure was used to control the significance level for multiple comparisons, ie, the significance levels .05 and .01 were divided by the number of comparisons, which was three.[39]

RESULTS

Validation of methods. The amounts of each peptide expected to be present in the batroxobin and thrombin clots formed in vitro are shown in Table 5(A). In the case of the clot formed with thrombin, all FPA and FPB would be expected to be cleaved. For the batroxobin clot, only FPA would be removed and the amino terminus of the Bβ chain should be intact. Because each molecule of fibrinogen contains two Aα and Bβ chains, the expected molar amounts of the amino terminal peptides are double that of NDSK. The recovery of these peptides was >85% in each case, and was >90% for NDSK. When these data were treated as though these samples were unknowns, the calculated compositions given in Table 5(B) were obtained. These results show the expected predominance of fibrin I in the batroxobin clot and fibrin II in the thrombin clot.

Tissue samples. The samples examined and the surgical procedures from which they were obtained are shown in Table 1. The samples were classified histologically as acute or organized thrombi; fibrous, fatty, or complicated atheromatous plaques; or "normal" aortas.

Table 6 shows the fibrinopeptide content of the thrombi examined. The fibrinogen-related material determined immunologically as NDSK comprised 50% to 70% of the total protein as measured by amino acid analysis. In both acute and organized thrombi, the FPA content indicates that <2% of the NDSK was fibrinogen. The amount of releasable FPB in both groups was <5% of the NDSK, indicating that >95% of the Bβ1-14 peptide had been cleaved. Because 87% and 79% of the Bβ15-42 was present, the Bβ1-14 was cleaved by thrombin, leading to fibrin II formation, rather than by plasmin as Bβ1-42. No significant differences in the content of Bβ1-42 and Bβ15-42 or of releasable FPA and FPB were found when acute thrombi were compared with organized thrombi, indicating that they were biochemically similar at the NH_2-terminus.

Analysis of the aortic samples (Table 7) showed that <10% of the total protein was fibrinogen derived, ie, a 10- to 25-fold lower fibrinogen-related protein content than thrombi. The samples of normal aorta contained amounts of fibrinogen-related protein similar to those in the various types of plaques. In the samples of normal aorta, 79% of the fibrinogen Aα chains were intact. The amount of intact Aα-chain decreased from normal to fatty, from fatty to fibrous, and from fibrous to complicated plaques, suggesting an increase in Aα-chain proteolysis. The FPA content of complicated plaques was significantly less than that of normal aorta ($P < .01$), fatty plaques ($P < .01$), and fibrous plaques ($P < .01$). No significant differences in FPA content existed between normal aortas and either fatty or fibrous plaques or between fatty and fibrous plaques. The amount of

intact Bβ-chain in the normal aortas was 91% (mean of FPB and Bβ1-42) and was not significantly different in the fatty plaques, whereas fibrous plaques showed a significant increase of Bβ1-14 cleavage as compared with both fatty plaques and normal aortas ($P < .01$). Residual FPB in the complicated plaques represented only 5% of the theoretical maximum content and was significantly less than the FPB in the other groups ($P < .01$ for each), indicating that virtually all the fibrinogen was fibrin II or fragment X. No significant differences in the content of Bβ15-42 were detected between any of the aortic samples. The mean recovery of Bβ15-42 was 73% to 92% of the theoretical amount, based on the NDSK, again indicating that the major loss of Bβ1-14 was due to thrombin action at the Bβ14-15 bond rather than to plasmin action at the Bβ42-43 bond. A summary of the data expressed as percentages of fibrinogen, fibrin I, fibrin II, and fragment X in the NDSK (calculated as in Table 4) is shown in Fig 1.

Fibrin II and fragment X together represent >95% of the total fibrinogen-related protein in both acute and organized thrombi. Acute thrombi had a slightly higher proportion of fibrin II than did organized thrombi, whereas organized thrombi had a higher proportion of fragment X. The distribution of fibrinogen-related proteins in the complicated plaques was similar to that in organized thrombi, although, as shown in Tables 6 and 7, the fibrinogen-related proteins made up a much lower percentage of the total protein in the plaques and other aortic samples than in the thrombi. Fibrous and fatty plaques contained significantly more fibrinogen, and correspondingly less fibrin II and fragment X, than did complicated plaques. The NDSK in normal aortas consisted largely of fibrinogen, with small amounts of fibrin I, fibrin II, and fragment X.

DISCUSSION

The purpose of this study was to characterize the insoluble fibrinogen-derived material in thrombi and in atherosclerotic plaques. In vitro studies have shown that when fibrinogen is clotted with thrombin, fibrinopeptides A and B are released, leading to fibrin II formation.[3,4] A thrombus is believed to contain mainly fibrin II, but this has never been directly demonstrated. To this end, we developed a method to analyze the fibrinogen-derived material in tissues. The peptides and fragments released on thrombin and plasmin proteolysis were quantitated after CNBr degradation. Application of these techniques to clots formed in vitro demonstrated both satisfactory recovery of the fibrinogen-derived material and the retention of immunoreactivity of fibrinopeptides A, B, Bβ1-42 and Bβ15-42. Thrombin clots formed in vitro with plasmin inhibitors added consisted mainly of fibrin II, as expected.

The ability to distinguish between fibrin I and fibrin II was confirmed by the data from clots formed in vitro with thrombin or batroxobin (Table 5). In those experiments, the clots contained 6% to 8% fragment X. Because the clots were formed in the presence of aprotinin and soybean trypsin inhibitor, it is unlikely that plasmin was active during that stage. One possible explanation is that this may represent the minor fraction of circulating fibrinogen which has undergone partial degradation.[40]

When these techniques were applied to the examination of pathological human thrombi (Table 6), it was found that the thrombi formed in vivo had undergone proteolysis by thrombin in a manner very similar to that of thrombin clots formed in vitro. Acute and organized thrombi did not differ significantly in fibrinopeptide content. Both contained low amounts of fibrinogen and fibrin I, whereas fibrin II comprised >70% of the fibrinogen-related protein in both groups. Moreover, 50% to 70% of the protein content of the thrombi, measured by amino acid analysis, was fibrinogen-derived in both acute and organized thrombi, confirming that the conversion of fibrinogen to fibrin II is a major factor in thrombus formation.[16]

The polyclonal antiserum to NDSK used in the present study recognizes NDSK derived by CNBr treatment of

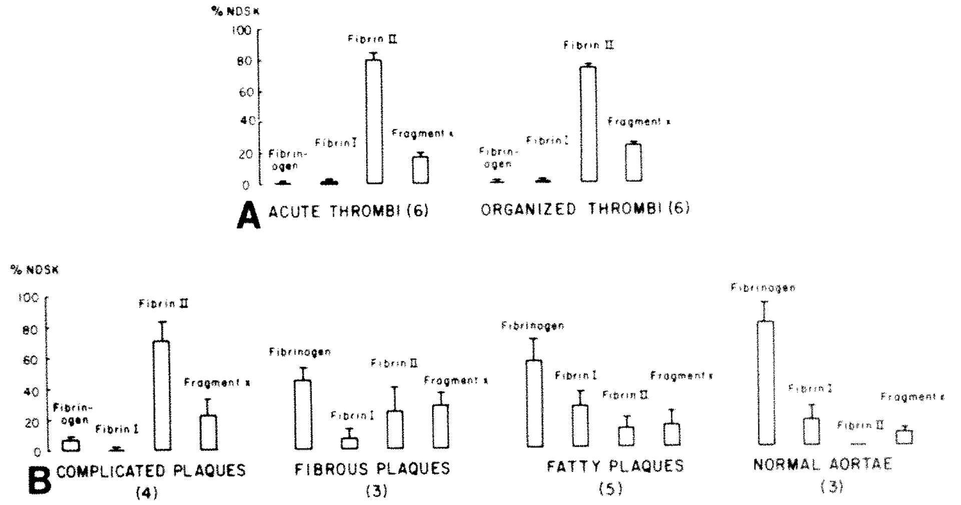

Fig 1. **The relative amounts of fibrinogen, fibrin I, fibrin II, and fragment X [expressed as a percentage of the NH_2-terminal disulfide knot of fibrinogen (NDSK)] for acute and organized thrombi (A), and complicated, fibrous, and fatty plaques and normal aortae (B).**

fibrinogen, fibrin, and fragment X, and CNBr-treated fragment E. Therefore, incomplete recovery of $B\beta 15$-42 in acute and organized thrombi can be assumed to reflect in vivo plasmin cleavage with fragment X formation in both groups. Fragment E formation in vivo would also be detected if the fragment E were noncovalently associated with the fibrin. Whether fragment X was formed by plasmin proteolysis of fibrin I or fibrin II cannot be distinguished in these studies. The comparable recovery of NDSK in the acute and organized thrombi indicates that plasmin cleavage of the NH_2-terminal ends of the fibrin in these thrombi was similar.

Francis and colleagues[7] reported a higher degree of lysis in older thrombi than in more recent ones. They[7] and others[5,6] examined lysis of the carboxy-terminal region of fibrin. Although in vitro studies in this laboratory have shown parallel cleavage of the NH_2-terminal $B\beta$ chains and the COOH-terminal $A\alpha$ chains of fibrinogen,[22] the relationship might be different for fibrin, with or without crosslinking.[41] In addition, the assays used in the present study do not allow distinction between fragment X and fragment E noncovalently associated with the thrombus.

Samples of aortic intima (Table 7) were very different from thrombi in their content of fibrinogen and fibrin-derived fragments. In all groups, the amount of fibrinogen-related protein was <10% of the total protein and was far lower than the 50% to 70% of total protein in thrombi.

The relative amounts of fibrinogen, fibrin I, fibrin II, and fragment X in the complicated plaques were not significantly different from those in the acute and organized thrombi, although the NDSK content was substantially lower. Both FPA and FPB were significantly lower in complicated plaques than in normal aortas or fatty or fibrous plaques, indicating that a significantly higher proportion of the NDSK in the complicated plaques as compared with the other aortic samples was derived from fibrin II. In contrast, the NDSK in normal aortas was derived largely from intact fibrinogen, and that in fatty and fibrous plaques appeared to be intermediate in its derivation from fibrinogen and fibrin I *v* fibrin II. The methods used to obtain the samples and the relatively small numbers of samples with specific diagnoses preclude the drawing of conclusions based on disease states.

The amount of fragment X in the complicated and fibrous plaques was slightly higher than that in the other aortic samples, but the amount of plasmin degradation was not large in any of the histologic types.

Previous studies have reported fibrinogen/fibrin in the aortic intima.[13-15,42] Quantitative comparisons between those studies and the present one are difficult because of methodologic differences in extraction and assay and in calculation and expression of results. In the present study, it has been possible to determine the molecular nature of the fibrinogen present. The total fibrinogen-related antigen is similar in normal aortas and complicated plaques, whereas the proportions of fibrinogen and fibrin II vary inversely with progression of the lesions. These results support the assertion that fibrinogen-related protein was present in the aortic samples in vivo, since in vitro or postmortem acquisition would be expected to show similar proportions of the different antigens. These results also raise the possibility that thrombin proteolysis of fibrinogen occurs within the intima, not only on the vascular surface with subsequent incorporation of fibrin into the intima. Recent studies have shown that fibrinogen can be crosslinked in vitro both by native and activated factor XIII in the presence of calcium ions,[43] and ex vivo studies suggested that the insoluble fibrinogen detected in aortic intima might be crosslinked.[14] Such crosslinked fibrinogen might be a good substrate for thrombin. If proteolysis of fibrinogen does occur within the vessel wall, the question of possible effects of the released fibrinopeptides on vascular endothelial and smooth muscle cells arises. In addition, the effects of cells present in normal aortas and in atherosclerotic aortas on the proteolysis of fibrinogen with the vessel wall must be considered.

Relatively little plasmin proteolysis of the NH_2-terminal end of the intimal fibrin had occurred. A higher degree of plasmin proteolysis of the COOH-terminal $A\alpha$-chains may have occurred; this possibility is being investigated in a companion study. Alternatively, little fibrinolytic activity may occur in the arterial wall, due to low levels of plasminogen activator in both normal and atherosclerotic arteries[44-48] or to high levels of plasminogen activator inhibitor in the arterial wall.[49]

In this study, we demonstrated that thrombi formed in vivo consist of fibrin II as Nossel postulated. The molecular changes in fibrinogen detected in the vessel wall with progression of lesions may result from the triggering of the clotting mechanism in association with the development and/or progression of atherosclerotic lesions. The low degree of plasmin proteolysis of the amino-terminal end of fibrinogen and the fibrin that was detected in both thrombi and plaques suggest either that proteolysis of the carboxy-terminal region occurs preferentially in vivo or that fibrinolysis is limited in the atherosclerotic vessel wall.

ACKNOWLEDGMENT

We are grateful to Dr Voorhees and the Vascular Surgery staff of the Columbia Presbyterian Medical Center for their help in collecting specimens. Drs Ralph Dell and Chris Zucker of the Department of Pediatrics of Columbia University performed the statistical analysis. Betty Grossman and Michael Drillings provided expert technical assistance for part of the work. We thank Helen Wegsman and Monique Rey for preparing the manuscript. We are very much indebted to the late Dr H.L. Nossel, whose ideas inspired this work.

Megakaryocyte Morphogenesis Stimulated In Vitro by Whole and Partially Fractionated Thrombocytopenic Plasma: A Model System for the Study of Platelet Formation

By Robert M. Leven and Marilyn K. Yee

Isolated guinea pig megakaryocytes were cultured in the presence of plasma from normal or thrombocytopenic rabbits. Thrombocytopenic but not normal plasma stimulated formation of long cytoplasmic processes and cytoplasmic fragmentation. Activity was found in the 60% to 80% ammonium sulfate fraction of thrombocytopenic plasma but not in the 0% to 60% fraction. The 60% to 80% fraction of normal plasma contained a small amount of activity. Both colchicine and vincristine inhibited the morphogenesis stimulated by thrombocytopenic plasma. Cytochalasin B and D both mimicked the thrombocytopenic plasma-induced morphological change and affected more megakaryocytes than did the thrombocytopenic plasma. Cytochalasin and thrombocytopenic plasma together had a synergistic effect, causing many megakaryocytes to form processes and break into cytoplasmic fragments 3 to 6 μm in diameter. Immunofluorescence staining with antitubulin antiserum showed that cytoplasmic processes formed in the presence of thrombocytopenic plasma contain microtubules and that fragments released by the megakaryocytes contain microtubule rings. A model for the cytoskeletal basis of platelet formation is proposed.

© 1987 by Grune & Stratton, Inc.

THE MATURATION of megakaryocytes culminates in fragmentation of their cytoplasm. The fragments are released into the circulation as newly formed blood platelets. The precise mechanism by which this process occurs is poorly understood. Megakaryocytes have a demarcation membrane system that partitions the cytoplasm of the cells into regions the size of platelets.[1-3] Fusion of these membranes around the platelet areas is believed to lead to the eventual breakup of the cytoplasm into many fragments that cross the endothelium and enter the blood as platelets.[4,5] An alternate mechanism of platelet formation has been proposed. Megakaryocytes in explants of bone marrow will on occasion produce numerous, long cytoplasmic extensions.[6,7] These extensions may have a beaded appearance; consequently, it has been postulated that these cytoplasmic arms break where most attenuated, liberating small fragments, thus forming platelets. This model of platelet formation considers the demarcation membrane system to be a store of membrane rather than a mere demarcation of future platelets.

Not only is the mechanism of platelet formation poorly understood, but neither is it clear whether there is any humoral control of this final stage of megakaryocyte maturation. Based on in vitro studies of megakaryocyte colony formation and in vivo studies on platelet formation, considerable evidence exists for humoral control of megakaryocytopoiesis. Interleukin-3 has been shown to stimulate megakaryocyte colony growth which is potentiated by various conditioned media.[8-10] Yet platelet formation does not normally occur in this type of culture. In vivo studies have shown that certain conditioned media[11] as well as plasma from thrombocytopenic and irradiated animals[12,13] contain an activity that stimulates megakaryocytopoiesis and platelet production when injected into test animals. This activity has been thought to be due to a hormone called thrombopoietin. Thrombopoietin activity has been partially purified from the plasma of thrombocytopenic rabbits,[14] but only one previous investigation has been made of the effect of thrombopoietin-enriched preparations on mature megakaryocytes.[15] This study indicated that DNA synthesis may be stimulated in megakaryocyte cultures when incubated with crude thrombopoietin.

In this study, data are provided to show that a crude thrombopoietin preparation stimulates the formation of long cytoplasmic processes and cytoplasmic fragmentation of isolated guinea pig megakaryocytes. Furthermore, the data provide the basis for a model of the mechanism of platelet formation.

MATERIALS AND METHODS

Megakaryocyte preparation. Megakaryocytes were isolated from Duncan Hartley guinea pig (Camm Laboratories, Wayne, NJ) bone marrow by modification[16] of the method of Levine and Fedorko.[17]

Rabbit plasma preparations. Blood was collected by puncture of the central ear artery from control New Zealand rabbits (R&R Rabbitry, Stanwood, WA) that had undergone no previous manipulations or from rabbits with immune thrombocytopenia. Thrombocytopenia was induced by the intravenous (IV) injection of 2 ml of guinea pig anti-rabbit platelet serum (a gift of Dr S. Ebbe). Prior to injection, a 0.5-ml sample of blood was collected to measure the hematocrit and platelet count. Hematocrits were measured using a Drummond microhematocrit (Drummond Scientific, Broomall, PA). Platelets were counted by the method of Brecher and Cronkite.[18] Four hours after antiserum injection, another 0.5-ml blood sample was drawn. If hematocrits were unchanged and the platelet counts were reduced to <20% of the count prior to antiserum

injection, the animals were bled by puncture of the central ear artery. Both normal and thrombocytopenic rabbits were bled using $^{1}/_{10}$ vol of 3.8% sodium citrate as an anticoagulant. Blood cells were pelleted by centrifugation at 500 g for 30 minutes. The plasma was centrifuged at 1,500 g for 15 minutes to remove any remaining platelets. The supernatant plasma from the normal (NRP) or thrombocytopenic animals (TRP) was either frozen or further processed as follows. All further steps were performed at 4°C. The plasma was brought to 60% saturation of ammonium sulfate using saturated ammonium sulfate solution with 0.1 mmol/L of etheylene glycol tetracetic acid (EGTA) pH 7.0. The precipitate was collected by centrifugation, and the supernatant was then brought to 80% saturation with ammonium sulfate. The precipitate was again pelleted. The 0% to 60% and 60% to 80% pellets were solubilized in phosphate buffered isotonic saline (PBS) pH 7.0, dialysed against PBS, and concentrated approximately fivefold by dialysis against dry sepharose. The fractionated plasma was then stored in aliquots at −20°C.

Cultures. Isolated megakaryocytes were cultured in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal calf serum (FCS) and 0.1 mg/mL of gentamycin at 37°C in a 5% CO_2–95% air atmosphere. All culture reagents were from GIBCO Laboratories (Grand Island, NY). The cells were generally cultured at 10^5 cells/mL in 35-mm Falcon culture dishes (Falcon Division, Becton Dickinson, Oxnard, CA).

Trypan blue staining. To test viability by exclusion of trypan blue, a sample of the megakaryocytes in culture were mixed with an equal volume of 0.4% trypan blue (GIBCO) in PBS. After 5 minutes, a drop of the cell suspension was placed on a microscope slide and a minimum of 100 cells were counted in each sample. Viable cells were considered to be those that did not stain. In addition, an equal volume of trypan blue solution was added directly to culture dishes to evaluate the staining of megakaryocytes without removing the cells from the culture dish.

^{51}Chromium release. Isolated megakaryocytes in liquid culture at 5×10^5 cells/mL were labeled by incubation with 75 μCi/mL of sodium ^{51}Cr (New England Nuclear, Boston, MA) (specific activity 295.3 mc/mg) for 1 hour at 37°C. After being labeled, the cells were washed three times by centrifugation. The first and second washes were in PBS pH 7.4. The third was in culture medium. The megakaryocytes were resuspended at 250,000 cells/mL in medium and aliquoted at 50,000 cells per well in a 96-well microtiter plate. Test substances were added directly to the wells. For spontaneous release, saline was added at the same volume as for thrombocytopenic and normal plasma fractions. Total release was measured by lysing cells with 3% sodium dodecyl sulfate (SDS). All samples were run in triplicate. The plates were incubated at 37°C for 3 hours, centrifuged at 400 g for 10 minutes; 0.1 mL of the supernatant was removed, and the radioactivity was measured in a TM Analytic Track 1193 γ counter. All measurements were corrected for background counts, and the specific toxicity was determined as 100 × (experimental sample cpm) − (spontaneous release cpm)/(total release cpm) − (spontaneous release cpm).

Immunofluorescence. Antitubulin immunofluorescence was performed by a modification of the method of Osborn and Weber[19] as previously described.[16] Antitubulin antiserum was from Miles Scientific, Naperville IL.

RESULTS

Effect of thrombocytopenic plasma on megakaryocyte morphology. Megakaryocytes were incubated for 18 hours after isolation. Either thrombocytopenic plasma (TRP) or normal rabbit plasma (NRP) was then added at 10% (5 mg/mL of protein) of the culture volume. The 60% to 80% ammonium sulfate fractions of the normal plasma (NRP 60 to 80) or thrombocytopenic plasma (TRP 60 to 80) were added at 1 to 2 mg/mL of final protein concentration; 0% to 60% fractions were added at the same concentration. Preliminary experiments indicated that higher concentrations did not increase the frequency of fragmenting cells; therefore, data were collected in cultures with 1 mg/mL of TRP 60 to 80 or NRP 60 to 80. Cultures were incubated for up to an additional 24 hours under these conditions, but data were collected after 3 hours of incubation since longer incubation times did not increase the number of fragmenting cells. NRP did not cause any change in the normal morphology of the cells; neither did the 0% to 60% fraction of NRP or TRP. NRP 60 to 80 caused a small percentage of the megakaryocytes to undergo fragmentation. TRP and TRP 60 to 80 stimulated fragmentation of a much higher percentage of the megakaryocytes (Table 1). The threefold increase in responsive cells in TRP 60 to 80 at one-fifth the protein concentration indicate an ~15-fold concentration of activity by the ammonium sulfate fractionation. Five hundred to 1,000 cells were counted in each dish to determine the percentage of cells forming processes or fragmenting. Only cells with a nucleus still visible were counted. Cell fragments not associated with a nucleus were not scored.

From 15 minutes to 1 hour after plasma addition, no morphological changes were observed. The first noticeable change in morphology occurred about 1 hour after addition of the TRP or TRP 60 to 80 and appeared to be maximal after 3 to 6 hours. There was considerable cell-to-cell variability in the reaction time. Megakaryocytes began to form processes that initially were 3 to 5 μm in diameter but that with time became much thinner and longer (Fig 1B). Eventually, the central region of the cells also began to partition until the entire cytoplasm was an irregular meshwork (Fig 1C and D). Occasionally, a cell would produce one long process, which could be as long as 500 μm but only 1 to 3 μm in diameter (Fig 1E). The processes often appeared beaded

Table 1. Effect of TRP and TRP 60–80 on Megakaryocyte Fragmentation

Culture Condition	Percentage of Megakaryocytes Forming Processes
Control (no additions)	0
NRP (10%)	0.1 ± 0.14*
TRP (10%)	5.4 ± 0.58
NRP 60–80 (1.0 mg/mL)	1.0 ± 0.82
TRP 60–80 (1.0 mg/mL)	18.4 ± 1.58
TRP 60–80 + 1 mg/mL of colchicine	5.0 ± 0.69
TRP 60–80 + 10 μg/mL of vincristine	3.7 ± 0.80

TRP, thrombocytopenic rabbit plasma; NRP, normal rabbit plasma.

Data are the averages from three experiments in which a minimum of 500 cells was counted for each condition. Each experiment was from a different megakaryocyte preparation. Colchicine and vincristine were added 1 hour prior to addition of TRP 60–80. Counts were made 3 hours after NRP, TRP, or TRP 60–80 addition. TRP was significantly greater than NRP ($P < .001$). TRP 60–80 was significantly greater than NRP 60–80 ($P < .005$). Inhibition was significant by both colchicine ($P < .01$) and vincristine ($P < .005$) as compared with TRP 60–80 alone.

*SEM.

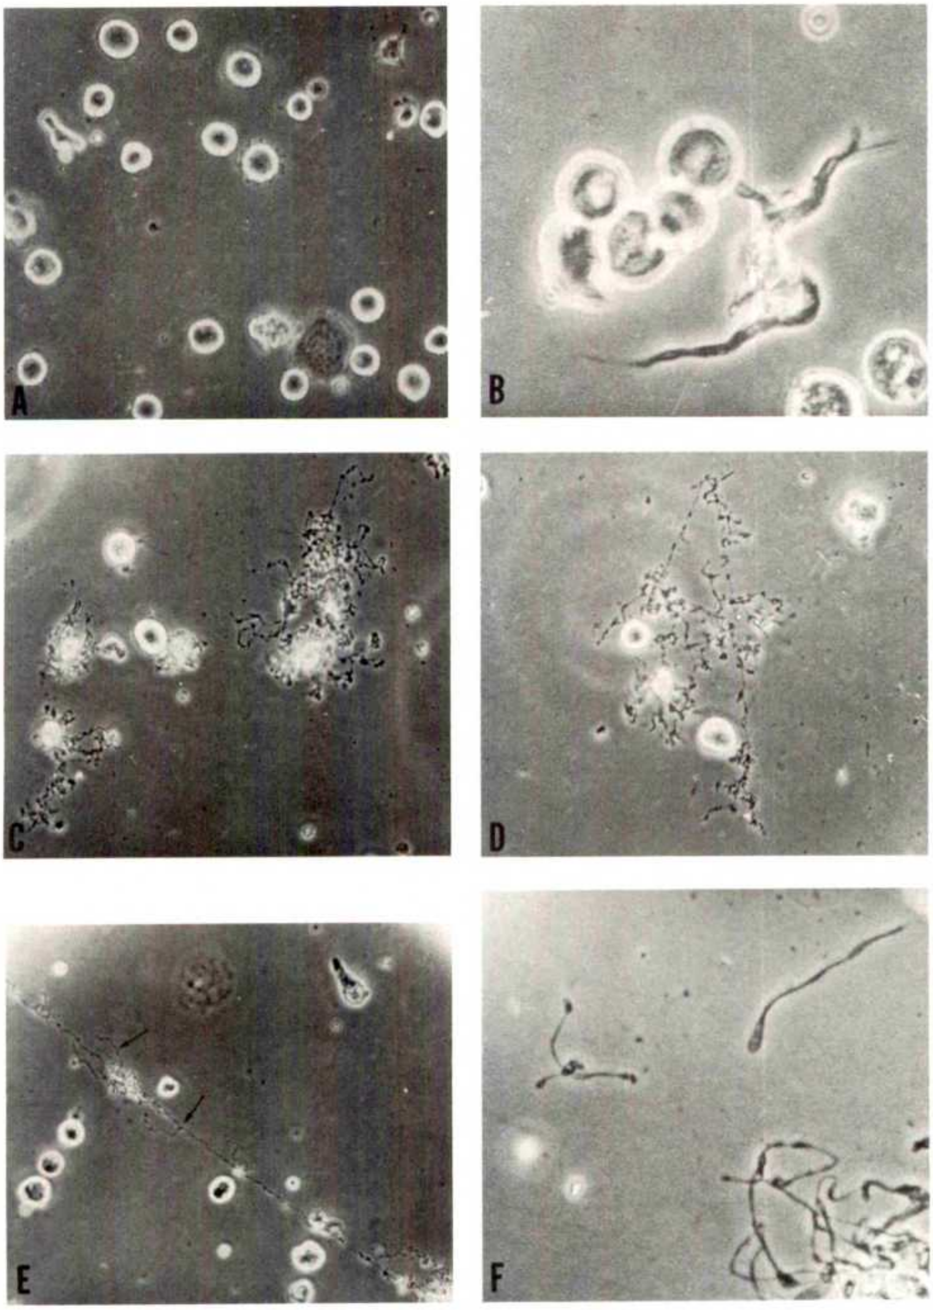

Fig 1. Response of megakaryocytes to the 60% to 80% ammonium sulfate fraction of thrombocytopenic rabbit plasma (TRP). Phase micrographs of isolated guinea pig megakaryocytes in liquid culture with 1.0 mg/mL of TRP 60 to 80. (A) Control megakaryocytes, no TRP 60 to 80 added to the culture. Cells maintained their spherical shape in control cultures until the cultures terminated due to senescence after 3 to 4 days. (Original magnification ×98.5.) (B) Megakaryocyte beginning to respond 1 hour after thrombocytopenic serum addition to the culture. Large cytoplasmic processes are beginning to form. (Original magnification ×395.) (C) through F) After 3-hour incubation in TRP 60 to 80. (C) Several megakaryocytes at a later stage of fragmentation. The entire cytoplasm is beginning to partition in these cells. (Original magnification ×60.) (D) Megakaryocyte prior to fragmentation. The cytoplasm is fully partitioned, and beading is evident along the cytoplasmic processes. (Original magnification ×160.) (E) Example of a megakaryocyte that has produced one very long cytoplasmic process. Several short branches are visible along the major process (arrows). (Original magnification ×175.) (F) Cytoplasmic fragments that have just been released by a megakaryocyte that is beginning to fragment. (Original magnification ×255.)

due to irregularly spaced thickenings clearly seen in the longer processes. Some cells eventually broke into fragments. On occasion, large fragments broke into smaller fragments (Fig 1F). Because the cells were in liquid culture, the smaller fragments were quickly carried away from the main cell mass. After 24 hours, few fragmenting cells were observed, possibly due to break up the fragmenting cells. Anti-rabbit platelet antiserum was added directly to cultures at a 1:75 dilution. This is comparable to the antibody dilution in a 3-kg rabbit with a 150-ml blood volume.[20] Cells were incubated with antiserum for up to 6 hours, and no change in cell morphology was observed.

Cell viability. Cell viability was measured in two ways; trypan blue staining and ^{51}Cr release. Megakaryocytes were incubated with TRP 60 to 80 or NRP 60 to 80 or with saline as a control. Table 2 shows that neither of these plasma fractions altered cell viability when measured by either trypan blue exclusion or ^{51}Cr release.

Effect of colchicine, vincristine, and cytochalasins. Megakaryocytes were incubated with either colchicine (1 mg/mL) or vincristine (10 μg/mL) for 1 hour prior to the addition of TRP 60 to 80. After additional incubation with TRP 60 to 80 for 3 hours, the percentage of fragmenting cells was determined. Neither colchicine nor vincristine alone altered megakaryocyte morphology, nor did 1.0% ethanol, the solvent for colchicine. When cultures were preincubated with these drugs prior to the addition of TRP 60 to 80, however, the number of fragmenting cells was sharply

Table 2. Effect of NRP 60–80, TRP 60–80 Colchicine and Vincristine on Megakaryocyte Viability

	Percentage Viable	
Trypan Blue Exclusion		
Control (no addition)	86.5 ± 1.36*	
NRP 60–80 (1.0 mg/mL)	83 ± 0.94	
TRP 60–80 (1.0 mg/mL)	85 ± 0.95	
Colchicine (1.0 mg/mL)	80 ± 0.77	
Vincristine (10 μg/mL)	89 ± 1.63	
	Specific Toxicity	
^{51}Chromium release	Exp 1	Exp 2
NRP 60–80 (1.0 mg/mL)	0	0
TRP 60–80 (1.0 mg/mL)	0	0.4

Abbreviations as in Table 1.

Data from the trypan blue exclusion experiments are average results of three experiments. Measurements are made in triplicate for each condition in each experiment. Viability in NRP 60–80 and TRP 60–80 with trypan blue was determined after 3-hour incubation. Viability in colchicine and vincristine was determined 3 hours after drug addition. None of the groups show any significant difference from the control ($P > .05$). Specific toxicity by Cr release was determined as described in the Materials and Methods section. Data show the results of two experiments in which measurements for each condition were made in triplicate. Cr release was measured after 3-hour incubation in TRP 60–80 or NRP 60–80.

*SEM.

decreased (Table 1). If the drugs were added after the 3-hour incubation with TRP 60 to 80, limited retraction of processes occurred. Neither drug affected cell viability, as determined by trypan blue exclusion (Table 2).

Cytochalasins had a very different effect on megakaryocyte morphology. Both cytochalasin B (10 μg/mL) and cytochalasin D(2 μg/mL) caused cytoplasmic process formation and partitioning of the megakaryocyte cytoplasm similar to that caused by TRP and TRP 60 to 80, (Fig 2). The morphogenesis with cytochalasins also occurred in 1 to 3 hours. There were two notable differences in the response to the cytochalasins. First, many more cells formed processes after incubation in the cytochalasins than in TRP or TRP 60 to 80. The percentage of cells responding was difficult to count accurately since many responding cells overlapped; thus, distinguishing individual cells was not always possible. Second, the cytoplasmic processes formed during exposure to cytochalasins tended to have a very smooth contour rather than the irregular beading that occurred in the presence of TRP or TRP 60 to 80. When megakaryocytes were incubated with either cytochalasin in the presence of TRP or TRP 60 to 80, there was an increase in the number of the megakaryocytes that formed processes with distinct beading

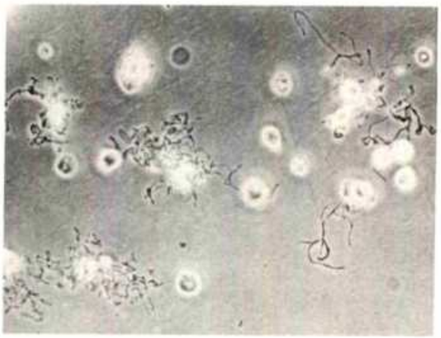

Fig 2. Isolated megakaryocytes in culture exposed to 2 μg/mL of cytochalasin D for 3 hours. Many megakaryocytes have formed cytoplasmic processes. (Original magnification ×250.)

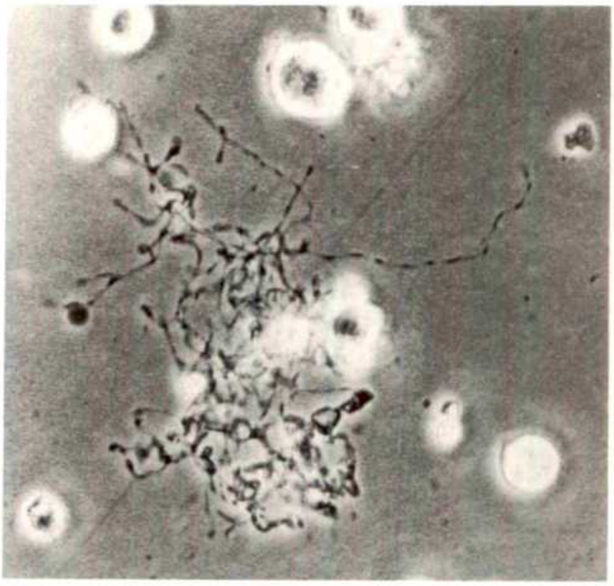

Fig 3. Megakaryocytes incubated with 2 μg/mL of cytochalasin D and 1.0 mg/mL of thrombocytopenic rabbit plasma (TRP) 60 to 80 for 3 hours. Many long processes have formed, and extensive partitioning of the entire cytoplasm has occurred. Beading is clearly apparent along the processes. (Original magnification ×275.)

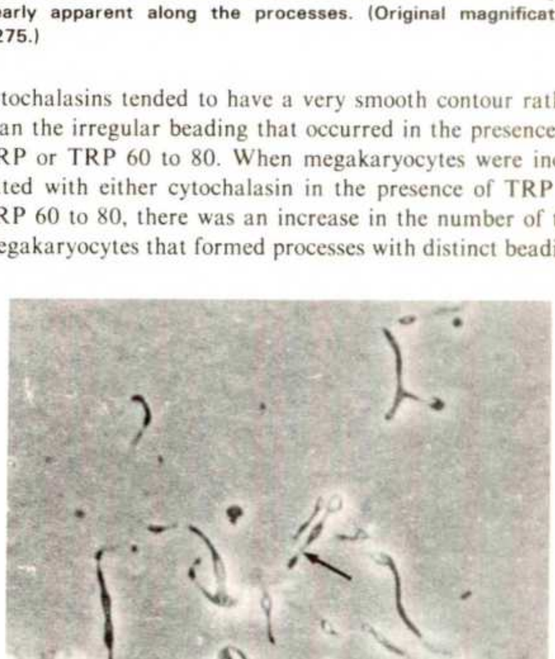

Fig 4. Megakaryocytes incubated for 3 hours with 1.3 mg/mL of thrombocytopenic rabbit plasma (TRP) 60 to 80 and 2 μg/mL of cytochalasin D. Several large proplatelet fragments have formed. Beading is evident on some fragments. (Original magnification ×250.) Many cytoplasmic fragments are visible. The diameters of fragments range from ~3 to 6 μm, and many are still attached by thin cytoplasmic threads (arrows).

(Fig 3). The cells appeared similar to those in TRP alone except for the increase in the number of responsive cells. Megakaryocytes commonly broke into large and small fragments under these conditions (Fig 4).

Tubulin immunofluorescence. Fragmenting megakaryocytes were observed by indirect immunofluorescence using antitubulin antiserum. The cytoplasmic processes were found to contain many microtubules extending along the long axis of the processes. The partitioning cytoplasm in the central area of the cell also contained microtubules. Microtubule rings were seen both in processes and near the cell body. Cytoplasmic fragments containing microtubule rings were also observed (Fig 5).

DISCUSSION

These results show that plasma obtained from rabbits with immune thrombocytopenia contains a factor that stimulates cytoplasmic fragmentation of isolated megakaryocytes. Thrombocytopenia has been shown to increase megakaryocyte maturation rate, number, size, and ploidy.[21-24] These changes occur over several days and are believed to depend on alteration of immature megakaryocytes and precursor cells. It has, however, been shown that a burst of large platelets is released within 18 hours of induced thrombocytopenia.[22] This more rapid response indicates that mature megakaryocytes may be directly affected in a thrombocytopenic state. The type of thrombocytopenic plasma preparation that we used stimulates platelet production in vivo,[12] but it is not clear whether mature megakaryocytes can be directly affected by thrombocytopenic plasma.

The megakaryocytes we isolated from bone marrow are recognizable megakaryocytes and not megakaryocytic precursors. Therefore, our observations show that megakaryocytes in the final stages of maturation are capable of responding to a factor that is increased in thrombocytopenic plasma within 4 hours of antiplatelet serum injection. Only one previous study investigated the effect of a thrombocytopenic plasma preparation on isolated megakaryocytes.[15] Stimulation of DNA synthesis was reported to occur during incubation in TRP 60 to 80; however, no observations were made on cell morphology. In our studies, up to 18% of the megakaryocytes fragment with TRP or TRP 60 to 80; therefore, it is possible that only a particular subpopulation of megakaryocytes responds to TRP. It would be interesting to know if megakaryocytes of a particular maturation stage or ploidy are the most responsive.

No fragmentation occurred when the cells were incubated with normal rabbit plasma, although a small amount did

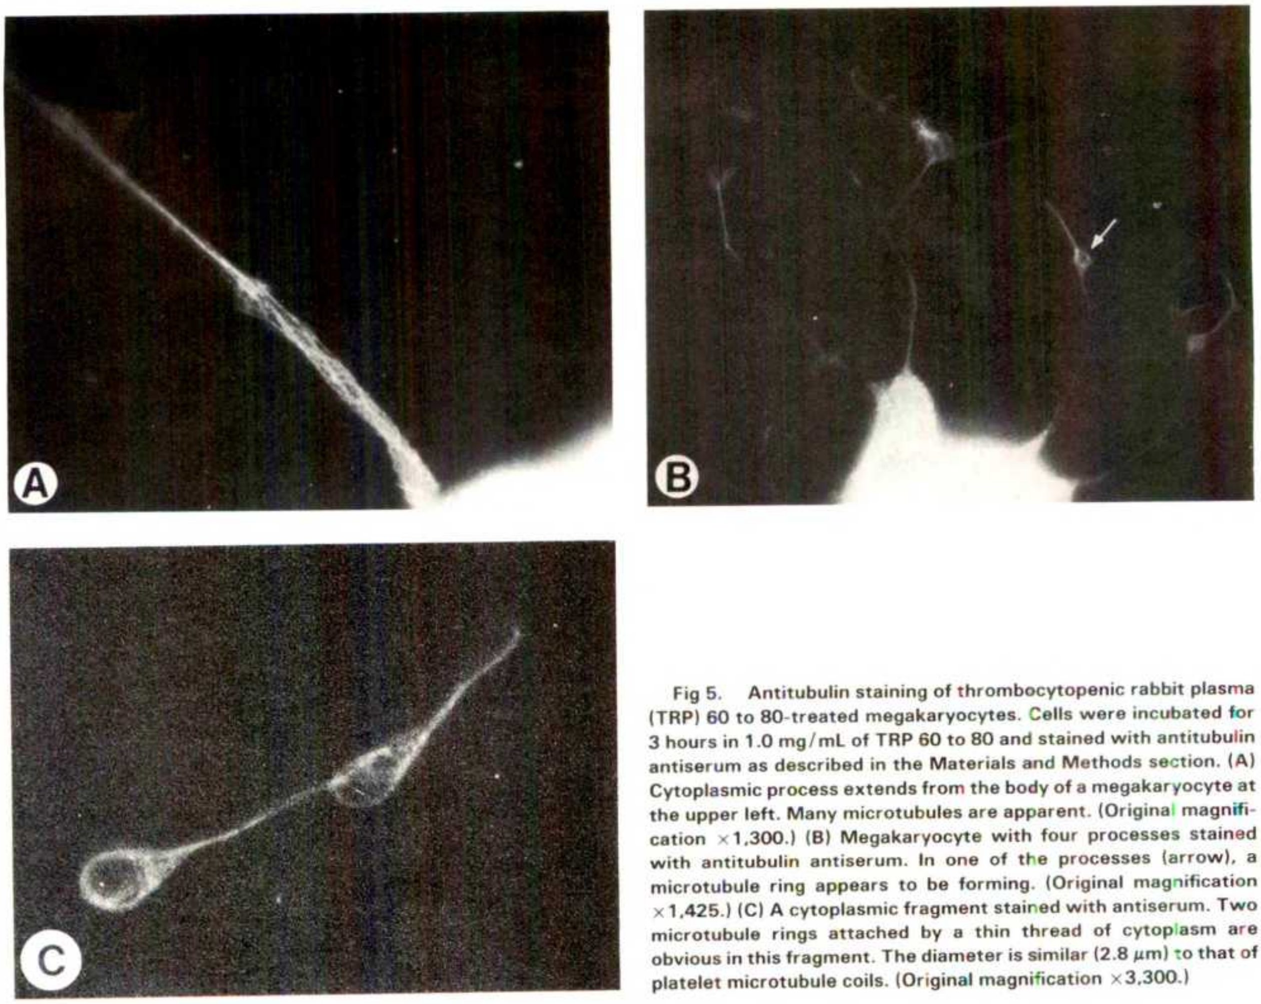

Fig 5. Antitubulin staining of thrombocytopenic rabbit plasma (TRP) 60 to 80-treated megakaryocytes. Cells were incubated for 3 hours in 1.0 mg/mL of TRP 60 to 80 and stained with antitubulin antiserum as described in the Materials and Methods section. (A) Cytoplasmic process extends from the body of a megakaryocyte at the upper left. Many microtubules are apparent. (Original magnification ×1,300.) (B) Megakaryocyte with four processes stained with antitubulin antiserum. In one of the processes (arrow), a microtubule ring appears to be forming. (Original magnification ×1,425.) (C) A cytoplasmic fragment stained with antiserum. Two microtubule rings attached by a thin thread of cytoplasm are obvious in this fragment. The diameter is similar (2.8 μm) to that of platelet microtubule coils. (Original magnification ×3,300.)

occur with NRP 60 to 80. It is possible that concentration of a reduced level of thrombopoietin which circulates in normal plasma was responsible for the small number of fragmenting cells. This is consistent with the observation that thrombopoietin activity can be detected in normal plasma when injected into platelet-hypertransfused test animals.[25,26] The fragmentation that occurs does not appear to be due to cellular toxicity. Using two independent methods to measure cell viability, we were unable to detect any decrease of viability in either NRP 60 to 80 or TRP 60 to 80.

The morphological change that occurs in megakaryocytes incubated with TRP or TRP 60 to 80 appears similar to the spontaneous morphogenesis of megakaryocytes observed by Thiery and Bessis[6] and by Radley and Haller.[7] Unlike these investigators, we observed no spontaneous process formation. In the absence of TRP and TRP 60 to 80, no morphological changes occurred in our cultures. The previous studies used teased marrow explants rather than isolated megakaryocytes. It may therefore be the presence of other marrow cells or factors in the marrow that allowed this spontaneous activity to occur.

On the basis of our findings and previous findings, we believe that megakaryocyte process formation is a microtubule-dependent phenomenon. Radley and Haller[7] observed that spontaneous cytoplasmic process formation was reversed by vincristine, and in our studies both colchicine and vincristine inhibited the TRP-induced morphogenesis. In addition, tubulin immunofluorescence showed that the cytoplasmic processes are microtubule-containing structures. Ultrastructural studies have shown that megakaryocytes in the marrow can form processes[27,28] containing aligned microtubules. Therefore, the formation of microtubule-based cytoplasmic processes is not likely to be an artifact of culture conditions but may be an important step in platelet formation. The presence of microtubule rings further supports the idea that the in vitro morphogenesis we observed is similar to platelet formation in vivo, particularly since the rings are seen not only in the cytoplasmic processes but also in some released fragments that are the size of platelets. We do not know if the fragments released are functional platelets, but the presence of microtubule rings implies that structural organization of the platelet cytoskeleton may occur at the time of, or possibly prior to, cytoplasmic fragmentation.

The cytoplasmic process formation and partitioning that occurred with cytochalasin was similar to that which occurred with TRP and TRP 60 to 80. The smooth surface of processes that form with cytochalasin indicate that TRP-induced and cytochalasin-induced morphogenesis may not be identical. Moreover, cytochalasins caused far more cells to begin fragmentation than did TRP or TRP 60 to 80. The active factor in TRP may stimulate megakaryocytes by a surface receptor that is not expressed on all cells. Because the cytochalasins diffuse into the cells and do not depend on a surface receptor, one would expect more cells to be affected.

From the data presented, we propose a model for the cytoskeletal basis of platelet formation. The factor stimulating fragmentation in TRP binds to a receptor on the surface of certain megakaryocytes, perhaps the most mature. Binding then triggers a change in the organization of actin in the cell. Actin filaments or filament networks, which maintain the cytoplasm intact, disassemble, causing the cytoplasm to change from a gel-like to sol-like state as postulated to occur in ameboid cells.[29] The disassembly of microfilament structures may be regulated by the actin regulatory proteins that have been identified in platelets[30-33] and probably exist in megakaryocytes as well. The processes that subsequently form have a core of microtubules and may elongate by polymerization of tubulin. We believe the long fragments of cytoplasm that form are comparable to the proplatelet processes observed by Behnke[23] and by Becker and De Bruyn.[34] What controls the fragmentation of proplatelets into platelets is still unexplained. A microfilament-based contractile mechanism is not likely to be involved since fragmentation occurs in the presence of cytochalasins. It is possible that other structural components determine the interval at which cytoplasmic processes fragment. The microtubule rings may play a role in controlling the intervals at which proplatelets break into platelets. Our model is similar to that of Becker and De Bruyn's interpretation of platelet formation,[34] although based on our results with megakaryocytes incubated with cytochalasins we do not believe actomyosin contraction is involved in forming processes as Becker and DeBruyn have proposed. Although speculative, our model of platelet formation is consistent with available data, and we believe it provides a useful basis for further study of the mechanism of platelet formation.

Stimulation by cAMP of Erythropoietin Secretion by an Established Human Renal Carcinoma Cell Line

By J.B. Sherwood, E.R. Burns, and D. Shouval

We used our recently reported stable, transformed human renal carcinoma cell line as a model system to study the role of 3′, 5′-adenosine monophosphate (cAMP) in erythropoietin secretion. The erythropoietin produced by these cells is both biologically active and immunologically cross-reactive with purified native human hormone in our radioimmunoassay. Erythropoietin release by these renal carcinoma cells appears to be stimulated by cAMP as well as by the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (MIX). The response to cAMP involves a rapid and enhanced release of hormone, which occurred within 30 minutes of exposure of the cells to the effector and continued for at least 4 hours. Intracellular erythropoietin was higher in the control cultures than in the cells treated with cAMP, suggesting that cAMP stimulates the release of a storage pool of hormone. The ability of cAMP and MIX to elicit the release of erythropoietin suggests that a cAMP-mediated mechanism is involved in the release of this hormone.

© 1987 by Grune & Stratton, Inc.

WE RECENTLY described[1] the development of a stable, transformed human renal clear cell carcinoma cell line that produces erythropoietin in vitro and that has maintained this function for several years and for >150 passages in culture. The erythropoietin produced by these cells appears to be biologically active in both the in vitro mouse CFU-E assay and in nude mice carrying the tumor. The tumor-produced hormone is detectable in our radioimmunoassay, and its ability to displace pure native human urinary hormone from the antierythropoietin antibody indicates that it shares structural similarities with the native protein.[1]

Considerable evidence supports a correlation between erythropoietin production in vivo and such parameters involved in oxygen supply as hemoglobin concentration, RBC mass, and ambient pO_2.[2] Little information exists, however, on regulation of erythropoietin synthesis and secretion at the cellular level. Our stable, established renal carcinoma cell line provides an excellent model system for studies of erythropoietin production at the cellular level. It also allows a comparison of regulation of hormone release by carcinoma *v* normal cells.

Cyclic 3′, 5′-adenosine monophosphate (cAMP) is known to regulate the release of many polypeptide hormones.[3] This effect has been observed in vitro for a number of hormones such as parathyroid hormone,[4-6] thyroid hormone,[7] and growth hormone.[8-10] A "first messenger" has been shown to act at the cell membrane to stimulate the membrane-bound adenyl cyclase, resulting in conversion of ATP to intracellular cAMP, which then acts to mediate hormone release.[3] In the case of erythropoietin, decreased oxygen levels may serve as a first messenger. We are therefore using our renal carcinoma cell line to examine the hypothesis that cAMP mediates an extracellular stimulus to erythropoietin production.

MATERIALS AND METHODS

Cells. The human renal carcinoma cell line designated as the RC-1 line was used for all studies. This line was derived from a renal cell carcinoma obtained in 1981 from a patient with erythrocytosis. These cells grow as a homogeneous monolayer, with neoplastic characteristics as evidenced by loss of contact inhibition and by the ability to be cloned and grown in soft agar.[1,11] The characteristics of this cell line have been fully described.[1] The current studies were performed on cells from several different passages (passages 37 through 105).

Cell culture methods. Tumor cells were routinely maintained in Corning tissue culture flasks (Corning Glass, Corning, NY) in complete medium, consisting of Dulbecco's modified Eagle's medium (DMEM) and nutrient mixture F12 (Ham) 1:1 by volume supplemented with 10% fetal bovine serum (FBS), 2 mmol/L of L-glutamine, 0.10 mmol/L nonessential amino acids, 100 U of penicillin, and 100 µg of streptomycin. All media components were obtained from Grand Island Biological (Grand Island, NY).

Radioimmunoassay of erythropoietin. Erythropoietin levels in the culture supernatant fluids and the cell extracts were determined in the radioimmunoassay described by Sherwood and Goldwasser.[12] The pure erythropoietin used as the radiolabeled tracer was described by Miyake and co-workers[13] and was generously supplied by Dr Eugene Goldwasser (University of Chicago) and by the Blood Diseases Branch, Division of Blood Diseases and Resources of the National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD. The erythropoietin was radiolabeled with ^{125}I, using the water-insoluble oxidizing agent 1, 3, 4, 6-tetrachloro-3α, 6α-diphenylglycoluril (Iodogen, Pierce Chemical, Rockford, IL),[14] to a specific activity of 16 to 21 μCi $^{125}I/\mu g$ of erythropoietin. The antibodies to erythropoietin were raised in New Zealand White rabbits in response to a preparation of crude human urinary erythropoietin. Human urinary erythropoietin (Toyobo, Osaka, Japan) was used as the standard in the assay. The methods for incubation of samples and antibody and for separation of antibody-bound and free erythropoietin by the second antibody technique were described previously.[12] The ratio of bound to total ^{125}I-erythropoietin was determined for the standard curve and for the culture and serum samples. All erythropoietin standards and unknown samples were assayed in triplicate. Medium with and without the experimental additives incubated without cells served as assay controls. Values are expressed as mean ±SEM, representing the replicate cultures.

Preparation of samples for detection of erythropoietin. Supernatant fluids obtained from culture dishes were centrifuged for 10 minutes at 1,000 rpm at 4°C in an IEC Centra 7-R tabletop

refrigerated centrifuge (International Equipment, Needham Heights, MA). The culture fluid was then stored at −20°C to −70°C until assay.

Cells were harvested from the cultures with 0.1% trypsin-0.1 mol/L of EDTA, washed with Earle's balanced salt solution (BSS), and extracted in 0.1 mol/L of phosphate buffer by homogenization with a Polytron (Brinkmann Instruments, Westbury, NY) as described by Sherwood and Goldwasser.[15] The cell extracts were stored at −20°C to −70°C until assayed.

Evaluation of effect of cAMP on erythropoietin production. For studies of erythropoietin production, cells were removed from the surface of the flasks by incubation with 0.1% trypsin-0.1 mol/L of EDTA, followed by resuspension in complete medium. The number of viable cells was determined in a hemocytometer, using exclusion of trypan blue dye as an indicator of viability. Each 60-mm Falcon tissue culture dish (Becton Dickinson, Cockeysville, MD) was seeded with 3×10^5 viable cells in 5 mL of complete medium and incubated at 37°C in 5% CO_2-95% air until confluence (1 to 2×10^6 cells per plate) was reached. The cultures were then incubated at 37°C in 5% CO_2-95% O_2 in a humidified tissue culture incubator (Forma Scientific, Marietta, OH) in 2 mL of "complete medium" containing 5% fetal bovine serum (FBS), and 8-bromo cAMP or the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (MIX) as indicated. Control cells from the same passage were incubated in the same medium (5% FBS), without cAMP or MIX, at the same time. Three replicate cultures were made for each effector concentration and time point. At the indicated times, cells and supernatant media were harvested, the viable cell count was obtained, and the erythropoietin was extracted from the cells as described. Erythropoietin levels in the media and cell extracts were determined by radioimmunoassay.

RESULTS

Effect of cAMP on intracellular and extracellular erythropoietin. Concentrations of 8-bromo cAMP $<10^{-5}$mol/L were ineffective in stimulating erythropoietin production. Therefore, in these studies, cells were incubated in experimental medium with or without 10^{-4}mol/L of 8-bromo cAMP for periods of 1 to 4 hours. As shown in Table 1, erythropoietin levels in the supernatant media from cAMP-treated cells were significantly higher ($P < .02$) than in the media from control cultures from the same passage incubated (at the same time) without cAMP. Conversely, erythropoietin levels in the cell pellets (intracellular erythropoietin) were significantly ($P < .02$) lower in the cAMP-treated cultures than in the controls. Control medium with and without 10^{-4}mol/L of 8-bromo-cAMP, incubated without cells, contained nondetectable amounts of erythropoietin (<10 mU/mL). The cAMP appeared to have no effect on cell morphology, growth, or viability.

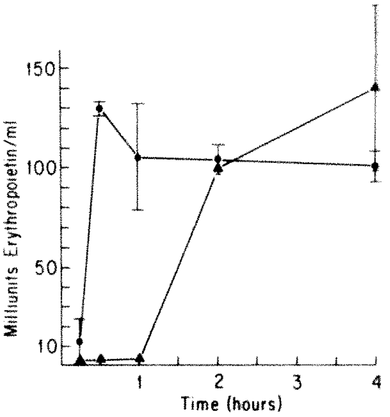

Fig 1. Effect of cAMP on the time course of erythropoietin secretion by the human renal carcinoma cell line: Cells from passage 105 were grown to confluence (~6 × 10^6 cells/60-mm plate) and incubated in standard culture medium with (●—●) or without (▲—▲) 10^{-4}mol/L of 8-bromo cAMP. At the times shown, the supernatant medium was harvested from three plates. Erythropoietin levels were measured in the radioimmunoassay. Each data point represents the mean for the replicate cultures, each measured in triplicate (SD generally ±10%).

Effect of 8-bromo-cAMP on time course of erythropoietin release. Cells from passage 105 were incubated in experimental medium with or without 10^{-4}mol/L of 8-bromo-cAMP. As shown in Fig 1, a slight secretory response to 10^{-4}mol/L of 8-bromo-cAMP was observed within 15 minutes (13 ± 10 mU/mL of medium) and reached a maximum at 30 minutes (130 ± 3 mU/mL). Erythropoietin levels in

Cells were incubated at confluence with 10^{-4} mol/L of 8-bromo cAMP in 2 mL of F12:Dulbecco's modified Eagle's medium. Erythropoietin values were determined in the radioimmunoassay. Each value represents the mean ± SEM for three plates, each measured in triplicate. All values are significantly different from values for control cells.

*ND, not detectable, <10 mU/mL. Control medium without cells had no detectable erythropoietin.

the medium remained constant for at least 4 hours (1 hour, 108 ± 27 mU/mL; 2 hours, 107 ± 7 mU/mL; 4 hours, 98 ± 8 mU/mL). The values for these time periods did not differ significantly ($P = .09$) from the 30-minute value. In contrast, erythropoietin was not detected in the supernatant medium of control cultures of the passage 105 cells until 2 hours of incubation (103 ± 3 mU/mL for 2 hours, 142 ± 42 mU/mL for 4 hours). The 4-hour value for the control cultures did not differ significantly ($P = .27$) from that of the cAMP-treated cultures from the same passage, suggesting some constitutive release by cells of this passage. No erythropoietin was detectable in the control media with and without cAMP, incubated without cells.

Effect of the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine on erythropoietin release. Cultures of passage-37 cells were incubated for 4 hours in experimental medium with 10^{-4}mol/L of MIX. After the 4-hour incubation period, the supernatant fluids were harvested; erythropoietin levels in the samples and in control medium containing the MIX but not incubated with cells were measured in the radioimmunoassay. Addition of either MIX or cAMP to the cultures was associated with erythropoietin levels in the supernatant medium that were significantly greater than in the control cultures: cultures with 10^{-4}mol/L of MIX, 48 ± 4 mU erythropoietin/10^6 cells; cultures with 10^{-4}mol/L of 8-bromo cAMP, 110 ± 1 mU/10^6 cells; control cultures, no detectable erythropoietin; and no detectable erythropoietin in the control medium incubated without cells.

Effect of long-term incubation on erythropoietin production by passage-37 cells. Cells from the passage 37 were incubated in experimental medium with and without 10^{-4}mol/L of 8-bromo cAMP, and the supernatant fluids were harvested after 4 hours and 24 hours of incubation. After 4 hours of incubation, erythropoietin levels in the supernatant media from cAMP-treated cells (110 ± 1 mU/10^6 cells) were significantly higher ($P < .02$) than in the medium from control cultures from passage 37 incubated without cAMP (nondetectable erythropoietin levels), whereas intracellular erythropoietin was higher in the controls (310 ± 38 *v* 118 ± 39 mU/10^6 cells). Control passage-37 cells did not appear to show constitutive erythropoietin release until 24 hours of culture; after 24 hours of incubation, erythropoietin levels in the medium were 38 ± 14 mU/10^6 cells in cAMP-treated cultures and 34 ± 10 mU/10^6 cells in controls (cAMP *v* control, P = NS). The cell content was higher in the cAMP-treated cultures (474 ± 84 mU/10^6 cells), however, than in the controls (118 ± 10 mU/10^6 cells).

DISCUSSION

This report describes the effect of 8-bromo-cAMP on the production of erythropoietin in vitro by our stable, transformed human renal carcinoma cell line[1] and provides evidence that cAMP is an intermediate in the regulation of erythropoietin production.

We described this cell line in a recent publication.[1] The cells have been maintained in culture since 1981 and for >150 passages and retain an abnormal human karyotype, ultrastructural features characteristic of human renal clear cell carcinoma, and the growth characteristics of transformed neoplastic cells.[1] The erythropoietic factor produced by this cell line appears to be biologically active in vitro, in the mouse CFU-E assay,[1] and in vivo, as demonstrated by the development of significant erythrocytosis in athymic Balb/c mice transplanted with cells from this line.[16] In our radioimmunoassay, displacement curves produced by increasing amounts of culture supernatant fluids were parallel to those produced by pure native human urinary erythropoietin, suggesting that the native human hormone and the tumor factor are similar.[1]

Little information exists on regulation of erythropoietin synthesis and secretion at the cellular level, in part due to the difficulty of establishing a suitable in vitro model system. Previously reported in vitro systems include cultures of normal kidney cells such as goat renal glomeruli[17] and rat mesangial cells,[18] as well as transformed cells such as the human renal carcinomas reported by Hagiwara and colleagues,[19,20] Sherwood and Goldwasser,[21] Sherwood and Shouval,[1,22] and Sytkowski and coworkers,[23] a human testicular carcinoma,[24] and mouse erythroleukemia cells.[25] Our studies represent the first reported use of a long-term stable human cell line to study regulation of erythropoietin production at the cellular level.

The membrane enzyme adenylate cyclase and its product cAMP are intermediates in the regulation of secretion of some polypeptide hormones.[3] The secretory effects of cAMP are mediated through activation of a cAMP-dependent protein kinase, leading to exocytosis of secretory granules.[26]

Erythropoietin production by our renal carcinoma cell line was stimulated by 8-bromo-cAMP and MIX. MIX, a cyclic nucleotide phosphodiesterase inhibitor, prevents the degradation of intracellular cAMP, thus allowing its accumulation.[5] The 8-bromo-cAMP used in these studies is a derivative of cAMP with an 8 substitution of the purine ring. Although these derivatives are able to inhibit cyclic nucleotide phosphodiesterase and to activate cAMP-dependent protein kinase, their primary mechanism of action at the cellular level is considered to occur by protein kinase activation.[27]

In these studies, cells were incubated with and without cAMP or with and without MIX, and erythropoietin production by cells of the same passage was measured by radioimmunoassay. Comparisons were made between cells of the same passage, not between cells of different passages. In all experiments and cell passages, erythropoietin levels in medium from cultures incubated with either 8-bromo-cAMP or with MIX were significantly higher than in medium from the control cultures of the same passage. In the short-term cAMP-treated cultures, the increased erythropoietin in the medium was associated with a concomitant decrease in intracellular hormone, in contrast to the control cultures—which had high intracellular and low media levels of erythropoietin.

cAMP produced a rapid and enhanced release of erythropoietin with 15 minutes of exposure of the cells to the nucleotide. Erythropoietin release continued to increase for ~30 minutes, after which the levels in the medium remained relatively constant (erythropoietin levels at the other times did not differ significantly from the 30-minute value). Erythropoietin release after 2 hours by the control cells of this passage suggests some constitutive production.

This pattern of erythropoietin release in response to elevated intracellular cAMP is similar to the response that has been observed for other hormones.[3,4-10,28] Addition of dibutyryl (db) cAMP at concentrations of $\geq 10^{-4}$mol/L to parathyroid gland explants resulted in significant stimulation of parathyroid hormone release 1 hour after incubation.[4,6] Growth hormone release from bovine pituitary gland anterior lobe explants[10] and cultures of rat adenohypophyseal somatotrophs[9] was stimulated within 30 minutes in response to elevated extracellular and intracellular cAMP and remained relatively constant during the 2-hour incubation period. cAMP also stimulates release of thyroid hormone,[7] thyroid-stimulating hormone,[8] insulin,[28] and calcitonin[28] in similar fashion.

cAMP stimulation may also lead to increased synthesis of some proteins.[3] In each experiment the total amount of erythropoietin in each culture (cellular content plus released hormone) was higher in the cAMP-treated culture ($P < .05$). This effect occurred in the cultures of passages 86 and 87 after 1 and 2 hours of incubation. Passage 37 cultures had similar total erythropoietin levels after a 4-hour incubation period. After 24 hours, however, the cAMP-treated cultures had a significantly higher intracellular erythropoietin content, but cAMP and control cultures had similar levels in the medium. Although cAMP effects are short-range phenomena in endocrine systems, cAMP may have some long-term effects on erythropoietin production[29,30] and on erythropoiesis.[31]

The increase in intracellular erythropoietin in the cAMP-treated cultures may be due to direct stimulation of synthesis by cAMP or may involve a feedback stimulus caused by depletion of an intracellular pool by the cAMP-induced hormone release. There may also be two intracellular pools of erythropoietin responsive to different physiological stimuli, one pool responsive to agents that elevate cellular cAMP and another pool responsive to other factors, as suggested also for parathyroid hormone.[32,33] As support for this, we showed that this cell line produces erythropoietin under control conditions (Table 1 and Fig 1), an observation that was important to us in developing this erythropoietin-producing line[1] in amounts and at time intervals that may differ for each cell passage. Some erythropoietin may also be released in a constitutive fashion, as has been reported for other culture systems.[1,19-24]

The short-term effects described in this report, increased erythropoietin in the medium within 15 minutes after cAMP stimulation associated with a concomitant depletion of intracellular erythropoietin (Table 1), are consistent with secretion of preformed erythropoietin. The immediate release of an intracellular pool of preformed hormone in response to cAMP stimulation has been extensively reported in other endocrine systems. The present studies substantiate the utility of this human renal clear cell carcinoma cell line for investigation of cellular factors mediating the production of erythropoietin.

Sardinian $\delta\beta^{\circ}$-Thalassemia: A Further Example of a C to T Substitution at Position −196 of the $^{A}\gamma$ Globin Gene Promoter

By Sergio Ottolenghi, Barbara Giglioni, Andrea Pulazzini, Paola Comi, Clara Camaschella, Anna Serra, Angelo Guerrasio, and Giuseppe Saglio

Selective overexpression (50- to 100-fold) in adult erythroid cells of either $^{G}\gamma$ or $^{A}\gamma$ fetal globin gene is observed in hereditary conditions known as $\delta\beta^{\circ}$-thalassemia and hereditary persistence of fetal hemoglobin (HPFH). Recently, a C → T change at position −196 of an overexpressed $^{A}\gamma$ globin gene from an Italian HPFH was hypothesized, on the basis of indirect evidence, to represent the cause of the functional defect. We now show that the same mutation is present in a different overexpressed $^{A}\gamma$-globin gene from a Sardinian patient with a different syndrome ($\delta\beta^{\circ}$-thalassemia). The Sardinian $^{A}\gamma$ globin gene differs from both the HPFH and the normal $^{A}\gamma$ globin gene at nucleotide 1,560 in the noncoding portion of the third exon, where an A is deleted. In addition, the mutant −196 $^{A}\gamma$-globin gene is linked to a normal β globin gene in HPFH, and to a β-thalassemic gene (β^{39}CAG → TAG) in $\delta\beta^{\circ}$-thalassemia. These data strengthen the suggestion that −196 mutation is causally linked to the abnormal phenotype and raise the question of whether the same or multiple mutational events are responsible for the appearance of the −196 mutation in different syndromes.

© 1987 by Grune & Stratton, Inc.

THE MOLECULAR mechanisms regulating the coordinated and balanced activity of the human non-α globin genes (ϵ, $^{G}\gamma$, $^{A}\gamma$, δ, β)[1] during developmental switches (embryonic and fetal),[2,3] cell maturation,[4,5] and in different cell populations (A and F cells)[6,7] remain almost completely elusive, despite the enormous wealth of structural information accumulated in the last few years.[8,9] Some information has been provided, however, by genetic studies of disorders of the level of the expression of γ and β globin genes, which suggested the existence both of *trans*-acting factors[10-12] and of *cis*-acting loci whose deletion can influence γ or β globin gene activity.[8,9,13-25]

More recently, attention has focused on nondeletion syndromes characterized by increased expression of either the $^{G}\gamma$ or $^{A}\gamma$ globin genes during the adult period.[16,26-29] These conditions can be distinguished as hereditary persistence of fetal hemoglobin (HPFH) and $\delta\beta^{\circ}$-thalassemia on the basis of the greater clinical severity and of the unbalance of the α/non-α chain synthesis ratio in the latter. Recently, a correlation between γ globin gene overexpression and the occurrence of a single point mutation in one or two regions upstream of the cap site (within 200 nucleotides), has been found.[26-30]

These mutations might prevent the normal suppression of γ-globin gene transcription occurring after birth, although no direct proof for this hypothesis has yet been provided. Here we report that the same mutation originally observed in an overexpressed $^{A}\gamma$ globin gene from a patient with HPFH[27] is now found in an unrelated patient with Sardinian $\delta\beta^{\circ}$-thalassemia.

MATERIALS AND METHODS

DNA obtained from a Sardinian $\delta\beta^{\circ}$-thalassemic heterozygous patient[16] was digested with restriction enzymes and hybridized with cloned probes as described previously[10] to distinguish the γ globin cluster corresponding to the $\delta\beta^{\circ}$-thalassemic chromosome.

*Bgl*II-digested DNA was enriched in a 13-kilobase (kb) fragment containing both γ globin genes by centrifugation on a 5% to 20% NaCl gradient, and the resulting DNA was ligated into EMBL 4 *Bam*HI-digested arms and packaged in vitro. After screening, γ globin clones lacking the *Hind*III polymorphic sites ($\delta\beta^{\circ}$-thalassemic) were subcloned into pBR322, and sequencing was carried out according to Maxam and Gilbert.[31]

RESULTS

Sardinian $\delta\beta^{\circ}$-thalassemia is a syndrome characterized by selectively increased (50- to 100-fold) expression of the γ globin gene during adult life (with fetal hemoglobin—Hb F = $\alpha_2\gamma_2$—levels ranging between 10% and 20%) and by complete absence of β globin production by the β globin gene in *cis*.[16,32,33] This condition has been observed so far only in patients of Sardinian origin. To investigate the structure of the overexpressed $^{A}\gamma$ globin gene, we cloned a 13-kb *Bgl*II fragment (containing both the $^{G}\gamma$ and the $^{A}\gamma$ globin genes) from a heterozygous patient into phage. Family studies of restriction enzyme polymorphisms in Sardinian $\delta\beta^{\circ}$-thalassemic patients indicate that both their γ globin genes are characterized by the absence of a *Hind*III polymorphic site[34] in the second intron; this allowed us to distinguish, in the patient studied, the $\delta\beta^{\circ}$-thalassemic gene from the normal $^{A}\gamma$ globin gene. The cloned $^{A}\gamma$ globin gene was completely sequenced, from position −270 upstream of the cap site, to position +370 after the poly A addition site. Two major normal $^{A}\gamma$ globin gene sequences are known, corresponding to chromosomes A and B with different evolutionary histories (refs 35, 36, and Slightom, Shen, and Smithies, personal communication, June 1984) and showing numerous inser-

tions, deletions, and single point mutations. The sequence of the thalassemic ${}^{A}\gamma$ globin gene closely matches that of the normal gene from chromosome B, with only two differences. The first mutation is a C-T substitution at position −196; the second mutation is the deletion of one nucleotide (A) at position 1,560 in the noncoding portion of the third exon (Fig 1); the same deletion is also found at the corresponding position of the ${}^{G}\gamma$ globin gene from chromosome B (Slightom, Shen, and Smithies, personal communication).

DISCUSSION

The C-T substitution at position −196 of the ${}^{A}\gamma$ globin gene which we detected in Sardinian $\delta\beta^{\circ}$-thalassemia may be responsible for the continued expression of this gene during adult life; alternatively, it may simply represent a polymorphic change with no relationship to the observed phenotype. We have previously described the same mutation in another overexpressed ${}^{A}\gamma$ globin gene that we detected in a Southern Italian patient with ${}^{A}\gamma$ HPFH.[27] More recently, Gelinas and colleagues[30] reported this mutation in an additional ${}^{A}\gamma$ globin gene from a Chinese patient with heterozygous ${}^{A}\gamma$ HPFH. On the other hand, in a collaborative study of HPFH and $\delta\beta^{\circ}$-thalassemia in Sardinia (with M. Pirastu, in preparation) the −196 mutation could be detected by oligonucleotide hybridization in $\delta\beta^{\circ}$-thalassemic patients only, but not in normal subjects, ruling out the hypothesis that this is a common polymorphism. Taken together, these results add further support to the idea that −196 mutation may be causally linked to ${}^{A}\gamma$ globin gene overexpression; it is of interest that two additional mutations, at position −202[26] and −198,[37] have been observed in overexpressed ${}^{G}\gamma$ and ${}^{A}\gamma$ globin genes, respectively, suggesting that a region around −200 may be relevant to γ globin gene regulation.

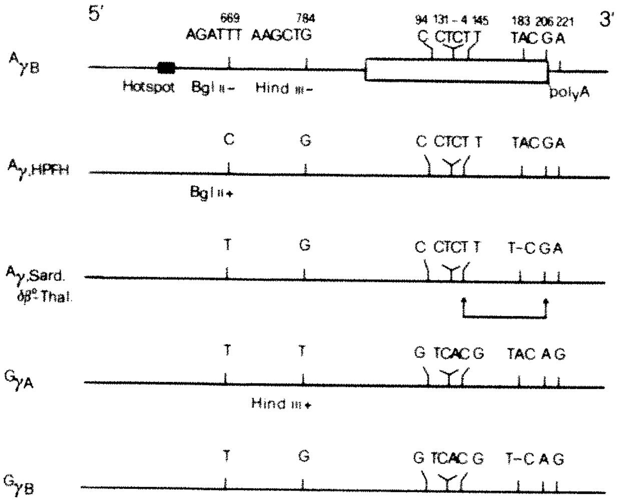

Fig 1. Nucleotide differences between Sardinian $\delta\beta^{\circ}$-thalassemia, Southern Italian hereditary persistence of fetal hemoglobin (HPFH), and normal γ globin genes. A normal γ globin gene is schematically represented. Numbers indicate nucleotide positions from the first nucleotide of the first exon and correspond to those given for the ${}^{A}\gamma$ globin gene from clone 165.24 in ref. 35. *BglII* and *HindIII* + or − indicate presence or absence of the corresponding restriction sites.[27,34] Nucleotide differences between the completely sequenced ${}^{A}\gamma$ globin genes from Southern Italian HPFH[27] and Sardinian $\delta\beta^{\circ}$ thalassemia (present article) and the normal ${}^{A}\gamma$ globin gene from chromosome B[35,36] are indicated. Also shown are nucleotide differences in the ${}^{G}\gamma$ (A and B) globin genes[35,36] *v* the normal ${}^{A}\gamma$ B globin gene; however, polymorphic differences 5′ to the *HindIII* site in the ${}^{G}\gamma$ globin genes are omitted for the sake of clarity. Gene conversion may have occurred between a ${}^{G}\gamma$ globin gene (type B) and the Sardinian $\delta\beta^{\circ}$-thalassemia ${}^{A}\gamma$ globin gene; arrows show limits of presumed event. The converted sequence cannot be longer than the distance (61 nucleotides) between positions 1,522 and 1,583 of the third exon, which are different in all ${}^{A}\gamma$ globin genes relative to ${}^{G}\gamma$ globin genes. C or G at position 1,471 is responsible for the insertion of alanine *v* glycine, respectively, in ${}^{A}\gamma$ and ${}^{G}\gamma$ globin chains.

The observation of the same mutation in three different overexpressed ${}^{A}\gamma$ globin genes raises the question of single *v* multiple origin of the mutation. It has already been suggested that several mutations of the β globin gene (β^{S}, β^{E}, $\beta^{\circ 39}$) occurred more than once.[9] The Chinese −196 HPFH mutation[30] occurs in a ${}^{A}\gamma$ globin gene of type A, whereas the mutations in the two Italian cases are in a gene of type B that differs at several positions from the former.[35,36] It is therefore likely that the Mediterranean and Chinese mutations have independent origins.

It is less clear whether the two Italian mutations have the same or independent origins. The two genes differ at only two positions. The Southern Italian ${}^{A}\gamma$ gene has a T-C substitution at position 1,180 in the second intron, generating a polymorphic *BglII* site that is absent in both the normal and the $\delta\beta^{\circ}$-thalassemia ${}^{A}\gamma$ genes. The second difference is the loss of A at position 1,560 in the noncoding portion of the third exon that is observed in the $\delta\beta^{\circ}$-thalassemic but not in the Southern Italian HPFH ${}^{A}\gamma$ globin gene. This deletion may be the result of a rather complex event, possibly a limited interchromosomal or intrachromosomal gene conversion that transferred a polymorphic feature characteristic of the ${}^{G}\gamma$ globin gene type B to the ${}^{A}\gamma$ globin gene (Fig 1) as demonstrated for several other polymorphisms[35,36,38,39] These data are equally compatible with either a single origin for the Sardinian $\delta\beta^{\circ}$-thalassemia and Southern Italian HPFH −196 mutations (followed by the occurrence of private mutations in each of the two genes) or with two independent mutations at position −196 in different genes.

In addition, although the HPFH mutant ${}^{A}\gamma$ globin gene is linked to a structurally normal β globin gene,[27] expressed at an almost normal level, the $\delta\beta^{\circ}$-thalassemic ${}^{A}\gamma$ globin gene is linked to a β°-thalassemic gene[40,41] carrying a $\beta^{\circ 39}$ nonsense mutation[42] that is usually not associated with increased Hb F production. If we postulate a single origin of the −196 mutation (described above), a crossing-over event linking together this overexpressed ${}^{A}\gamma$ globin gene from an HPFH chromosome with a β-thalassemic gene must have occurred. The existence of a "hot spot" for crossing-over within a 9-kb region between the $\psi\beta$ and β globin genes has been previously suggested[9,43]; such a crossing-over would be compatible with the observed haplotypes (Fig 2).

Although we have no formal proof for this series of events, this hypothesis might be testable by looking for overexpressed −196 ${}^{A}\gamma$ globin genes unlinked to β°-thalassemia in the Sardinian population.

Remarkably, the Sardinian $\delta\beta^{\circ}$-thalassemia case is the first instance in which the joining of an overexpressed γ

Fig 2. The $^A\gamma$-δ-β globin cluster in Southern Italian hereditary persistence of fetal hemoglobin (HPFH), Sardinian $\delta\beta^\circ$-thalassemia and β°-thalassemia (β^{39} nonsense mutation). Average Hb F and Hb A$_2$ percentages observed in heterozygotes are indicated. Several different γ globin genes (always producing low levels of γ globin) are linked to the β-thalassemic gene. All normal $^A\gamma$ globin genes sequenced so far have C at position −196, although direct data for $^A\gamma$-globin genes *cis* to β^{39} mutation are not available; however, preliminary hybridization experiments with specific oligonucleotides confirm this data. Restriction enzyme polymorphisms for β°-thalassemia (β^{39}-mutation) are from ref. 9 and M. Pirastu, personal communication. (Istituto di Clinica e Biologia dell 'ETA' Evolutiva, Caguari, Italy, September 1986).

globin to a β-thalassemic gene (whatever its mechanism) can be demonstrated to have significant physiological and possibly evolutionary effects; indeed, the high level of γ globin synthesis, by partially compensating for the decreased β globin synthesis, changes the severe β°-thalassemia phenotype (lethal in homozygous form) into a relatively mild condition that may be compatible with survival without transfusion in $\beta^\circ/\delta\beta^\circ$-thalassemic compound heterozygotes.[32] Considered in an evolutionary light, it is significant that although the overexpressed $^A\gamma$ globin gene of Southern Italian HPFH is very rare (only two families yet detected) in Southern Italy, the same gene in the $\delta\beta^\circ$-thalassemic context is relatively frequent in Sardinia (gene frequency: 0.1%) and represents a relatively high proportion (1.2%) of all β-thalassemic genes.[44] This fact suggests that the mutant $^A\gamma$ globin gene, because of its linkage to a β-thalassemic gene (that was under positive selection in this area) or because of the new phenotype (β-thalassemia with high fetal hemoglobin) may have conferred a selective advantage (relative to the normal and possibly also to the β-thalassemic population) to the carriers.

Heterozygous Sardinian $\delta\beta^\circ$-thalassemic patients exhibit, in addition to β°-thalassemia, normal or slightly decreased Hb A$_2$ levels, contrasting with the increased Hb A$_2$ level commonly observed in β-thalassemic heterozygotes. This finding may suggest the coexistence of a δ-thalassemic mutation; however, it has been observed that the expression of δ and β globin genes in *cis* to the −196 and −202 HPFH mutations is decreased, although direct determination of the nucleotide sequence of the β globin gene in Southern Italian $^A\gamma$ HPFH[27] and functional tests in $^G\gamma$ HPFH[26] indicate normality of the β globin genes. These data suggest that the decreased activity of β and δ globin genes in the latter syndromes (and of the δ globin gene in Sardinian $\delta\beta^\circ$-thalassemia) may be secondary effects somehow related to the hyperactivity of the mutated γ globin gene in *cis*.

ACKNOWLEDGMENT

We thank J. Slightom for communicating his complete sequence of $^A\gamma$ globin genes (chromosomes A and B), and L. Luzzatto for comments and suggestions.

Development of T3/T Cell Receptor Gene Expression in Human Pre-T Neoplasms

By Stefania Pittaluga, Michael Uppenkamp, and Jeffrey Cossman

Acquisition of mature T cell function and the T cell antigen receptor repertoire occur in the thymus. In an effort to delineate the cascade of events leading to T cell maturation, we analyzed a series of clonal human precursor T cell neoplasms representing early, middle, and late stages of intrathymic differentiation. Rearrangements of the T cell receptor β and γ genes appear concurrently and are preceded by surface expression of the 3A1 (CD7) molecule. Subsequent transcription of the β gene is coordinated with surface expression of T1 (CD5) and T11 (CD2), transcription of T3δ mRNA, and the appearance of intracellular T3 (CD3) protein. As late events, Tα gene transcripts appear and, finally, T3, the multichain complex linked to the T cell receptor, is presented on the cell surface. Findings reported here provide a model of the developmental orchestration of genes encoding antigen recognition in human T cells.

INTRATHYMIC T cell differentiation involves a multistep pathway featuring the rearrangement and transcriptional activation of genes encoding antigen recognition. Prior to expression of the cell surface membrane T cell antigen receptor (TCR),[1] genes encoding their α (T_α) and β (T_β) subunits must undergo successful variable region rearrangement, and their translational products combine with the multichain protein, T3.[1-11] Independent investigations of murine and human immature T cells implicate a hierarchy of events in which transcription of the T_β gene occurs early, persists throughout thymocyte development, and precedes the onset of T_α gene transcription.[12-18] Transcripts of a third rearranging gene, T_γ,[19-25] have been detected in fetal murine thymocytes, approximately coincident with the appearance of T_β mRNA, but, except for some murine cytotoxic T cells, remain for only a brief time.[17,18]

An ontogenic hierarchy of TCR α, β, and γ gene rearrangements analogous to immunoglobulin heavy, κ, and λ genes[26,27] might be suspected, but little information exists in this regard. Both T_γ and T_β genes rearrange early in thymic development,[18,21] but the ontogeny of T_α gene rearrangements has not yet been determined because murine and human J_α regions are too large (~35 kilobase [kb]) for conventional restriction fragment analysis.[6,28,29] With regard to T3, immunoreactive T3 protein appears to accumulate in the cytoplasm before surface expression when assayed in normal and neoplastic T cells.[30]

In addition to the development of antigen receptors, maturing thymocytes express a series of differentiation stage-related surface molecules, detectable with monoclonal antibodies, eg, T6 (CD1), T11 (CD2), T1 (CD5), and 3A1 (CD7) markers, which are useful for defining selected stages of early T cell differentiation.[31,32] Although the role of these cell surface molecules in T cell development is not known, some cell surface molecules apparently are coordinately expressed with the TCR-T3 developmental cascade. For example, cell surface expression of 3A1 (CD7) can be found in neoplastic precursor T cells prior to T_β gene rearrangement,[33] whereas other T cell-associated surface molecules generally appear only after T_β rearrangements occur.[33,34]

To determine the sequence of rearrangement and transcription of the TCR_α, β, and γ genes in humans, we investigated a series of human precursor T cell neoplasms representing early, middle, and late stages of thymocyte differentiation. These studies revealed a hierarchy of rearrangement and expression of TCR genes synchronous with changing surface marker profiles and expression of the T3 complex. Analysis of pre-T neoplasms suggests a model of successively expressed genes coordinated with development of the TCR mechanism.

MATERIALS AND METHODS

Cells. T lymphoblastic neoplasms were classified by conventional microscopy as either acute lymphoblastic leukemia or lymphoblastic lymphoma and immunotyped as T cell lineage as described.[33] Viable cell suspensions were used for cell surface marker study and DNA/RNA extraction. T acute lymphoblastic leukemia cell lines, provided by the American Type Culture Collection (Rockville, MD) included CEM, 8402, Molt-4, and Jurkat.

Cell surface phenotyping. Viable cells were treated with monoclonal antibodies and analyzed by indirect immunofluorescence in a fluorescence-activated cell sorter (FACS II, Becton Dickinson, Sunnyvale, CA) as described.[35] Cytoplasmic staining of T3 was performed on acetone-fixed cytocentrifuge preparations with an avidin–biotin complex immunoperoxidase detection technique as previously outlined.[35]

DNA/RNA analysis. High-molecular-weight DNA was extracted from lymphoid cells and digested to completion with the appropriate restriction endonuclease (*Bam*HI, *Eco*RI, *Hind*III, and *Bcl*-I from Biolab, New England Nuclear, Beverly, MA), size-fractionated by electrophoresis in agarose gels, and transferred to nylon paper (Gene Screen Plus, Dupont, New England Nuclear).[33] The blots were hybridized with random-primed ^{32}P-labeled DNA probes at specific activities of 300 to 600 cpm/pg. The following probes were used: a subcloned constant region of the β chain (*Ava*I-*Pst*I fragment of cDNA YT35 provided by T. W. Mak[2]), a full-length cDNA of T_α (PY14 provided by T. W. Mak[6]), and a genomic fragment including the J_1 region of the human T_γ gene (*Hind*III-*Eco*RI fragment of M13H60 provided by T. Rabbitts.[22,24]) Blots were autoradiographed following high-stringency washes.

Total cellular RNA was isolated by ultracentrifugation on a guanidinium isothiocyanate/$CsCl_2$ gradient.[36] Twenty micrograms

of total RNA was subjected to electrophoresis through 1% agarose/formaldehyde denaturing gels and was transferred to nylon filters. Hybridization was carried out with probes described above and also with a human $T3_\delta$ cDNA[37] provided by C. Terhorst, Harvard Medical School. High-stringency washes were carried out at 50°C in 0.1X SSC for 15 minutes, and blots were autoradiographed by standard techniques.

RESULTS

Phenotyping. All samples were unreactive with all B cell markers and expressed one or more T cell markers (Table 1). Each strongly reacted with 3A1 (CD7), but other T cell markers were selectively expressed in these early T cell neoplasms. For example, T11 (CD2) was negative in 2 cases (1 and 3) which alternatively expressed T1 (CD5); T6 (CD1), a marker expressed by cortical thymocytes, was unreactive in 5 of 10 samples (1, 2, CEM, 8402, HSB); and surface T3 (CD3) was positive in only 2 of 10 samples. In contrast, intracellular T3 was detectable in all but 3 cases (1, 2, and 3) and displayed a combined nuclear membrane and cytoplasmic distribution (Fig 1).

DNA rearrangements. T_β gene rearrangements were demonstrated in three of five primary cases and in all cell lines. Cases 1 and 2 displayed only germline configurations of the T_β genes when analyzed with three different restriction enzymes (*Bam*H1, *Eco*RI, and *Hind*III), as previously reported.[33] T_β gene rearrangements involved a single allele (cases 3, 5, and Jurkat) or both alleles (in all cell lines) and, in one exceptional situation, three nongermline T_β bands and deletion of the germline band (case 4). This latter feature was confirmed by analysis with all three restriction endonucleases. By cytogenetic analysis, case 4 exhibited trisomy of chromosome 7, which carries the T_β locus at band 7q35[38-40]; thus, the three nongermline bands are most likely a consequence of rearrangements of each T_β gene in this cell.

Rearrangements of the T_γ gene were detected in all cases and cell lines, except for cases 1 and 2 (Table 1, Fig 2). Thus, the presence or absence of T_γ and T_β gene rearrangements coincided in each sample tested. Case 4, which harbored a trisomy of chromosome 7, showed three different rearrangements of the T_γ gene, as it did for T_β. Presumably, the three nongermline bands are due to three copies of the T_γ gene, located at chromosome 7p15.[23]

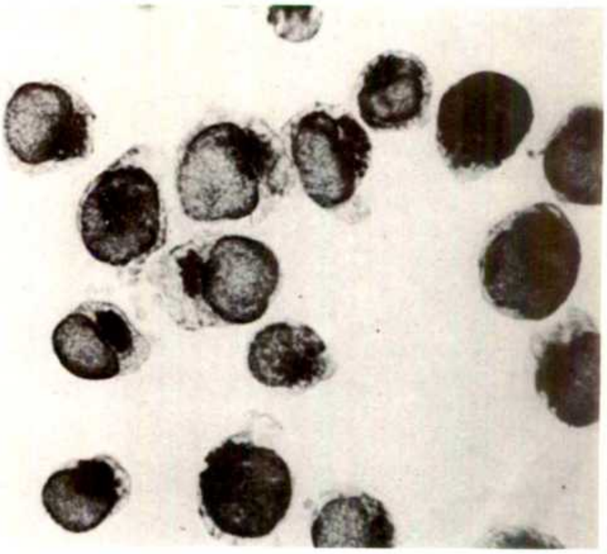

Fig 1. Intracellular T3 (cT3). Cytocentrifuge preparations were immunostained by an avidin-biotin peroxidase complex detection system using Leu4 as the primary antibody. In this example Jurkat cells display dense, intracytoplasmic, perinuclear reaction product. In many cells the nuclear membrane also appears to be stained. (Original magnification, ×600; current magnification ×570.)

T_α gene rearrangements were undetected in many cases, including cases 1 and 2, despite digestion with several restriction enzymes (Fig 3). Lack of nongermline bands might be due to either unrearranged T_α genes or to the unusually large size of the T_α genome.[6,28,29] We were able to identify a T_α rearrangement in Jurkat and a deletion of a T_α band in Molt-4.

mRNA transcription. T_β mRNA was detectable in each sample (Fig 4) except cases 1 and 2, which contained germline T_β genes. Case 3, with an early phenotype (3A1+, T11−, T1+) but a rearranged T_β gene, showed only the incomplete or "immature" 1.0-kb T_β message, presumably transcribed from a C_β gene that had not combined to variable

+, >50% of cells stained; −, <20% of cells stained; cT3, intracellular T3; sT3, surface T3; G, germline; R, rearranged; D, deleted; —, none detected; mRNA sizes are given in kilobases.

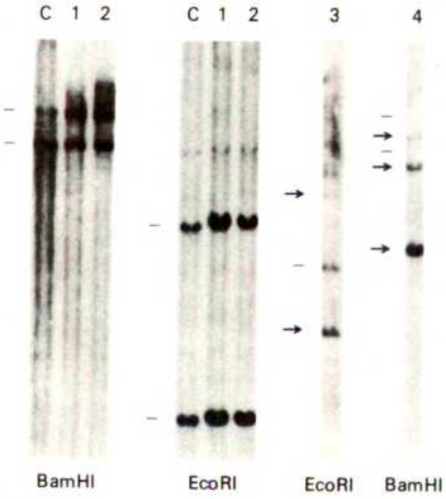

Fig 2. T$_\gamma$ gene rearrangements. Genomic DNA was digested with the indicated enzyme, size separated in agarose gels, and analyzed on Southern blots with the J$_\gamma$ probe. Lanes are numbered according to the case number, C represents a germline (unrearranged) control, and the germline bands are indicated with dashes adjacent to the gel. No rearrangements were detected in either case 1 or 2 when digested with both enzymes *BamHI* or *EcoRI*. Rearrangements were detected in all other cases; for example, two rearrangements were seen in an *EcoRI* digest of case 3, and three rearrangements were present in a *BamHI* digest of case 4.

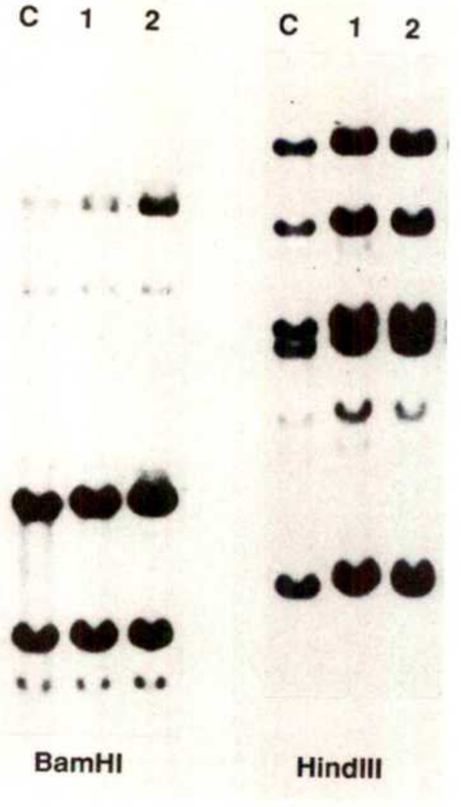

Fig 3. Southern blot analysis of the T$_\alpha$ gene. Despite digestion with two different restriction enzymes, *BamHI* and *HindIII*, both cases 1 and 2 showed the same restriction fragment as the germline control (C).

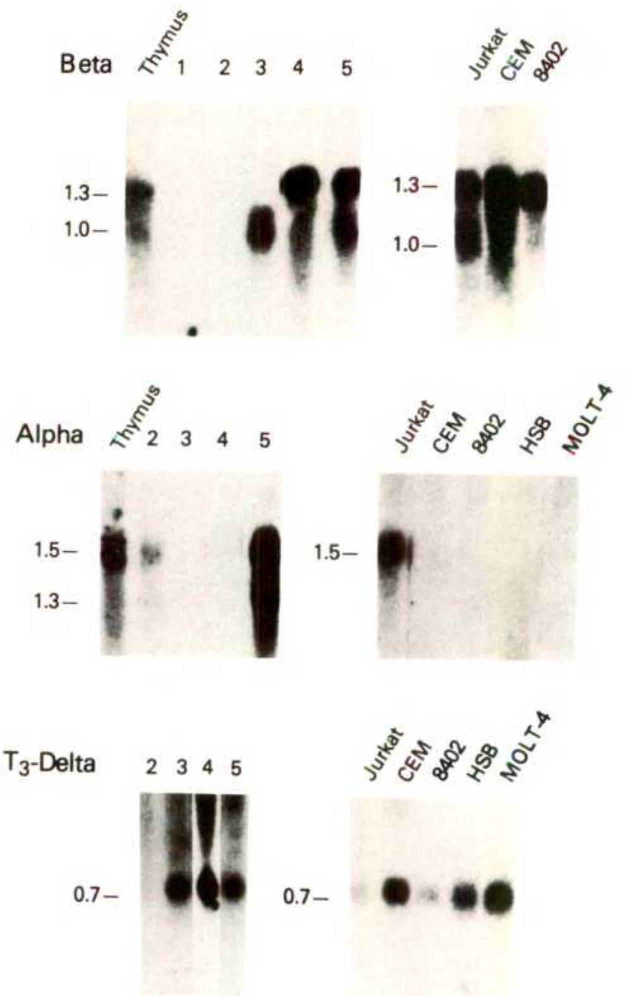

Fig 4. Northern blot analysis of β, α, and T3δ mRNA. Lane numbers refer to the individual case numbers, and mRNA sizes are given in kilobases (kb) on left. β Transcripts were detected in all samples except cases 1 and 2. Both the 1.3-kb and 1.0-kb message sizes could be detected in several cases. T$_\beta$ transcripts were detected in normal thymus, case 5, and in the Jurkat cell line. No transcripts were seen in either cases 3 or 4, and the extremely faint band in case 2 appearing after prolonged exposure is most likely attributable to a small percentage of normal T cells (~7%) contaminating this sample. T3δ mRNA was found in varying abundancy in most cases but was not detected in cases 1 or 2.

sequences.[41] Both mature (1.3 kb) and immature (1.0 kb) T$_\beta$ messages were simultaneously present in case 5 and in Jurkat.

T$_\alpha$ mRNA was detectable only in case 5 and in Jurkat and, in each of these leukemias, both the incomplete (1.3 kb) and mature (1.5 kb) messages were transcribed (Fig 4). These two T cell neoplasms containing T$_\alpha$ transcripts, case 5 and Jurkat, were also the only cells with surface T3 expression. T$_\gamma$ mRNA was not detected in any samples tested.

T3δ transcripts 700 base pairs (bp) in length were detected in all samples except cases 1 and 2, which were also the same leukemias devoid of detectable intracellular and surface T3 protein (Fig 4). Intracellular T3 protein and T3 mRNA were simultaneously present in all other samples.

DISCUSSION

T lymphoblastic leukemias and lymphomas are relatively uniform clones considered to be arrested at intrathymic stages of differentiation; they generally reflect the phenotypically characterized compartments of early T cell ontogeny.[31] Together, lymphoblastic malignancies of T and B cell lineage represent neoplasms of lymphocyte precursors and thereby serve as models for the evaluation of lymphocyte development.[12-14,26,30,31,33-35,42] The understanding of the development of immature thymocytes into mature, functional T cells has been expanded by analysis of precursor T cell neoplasms obtained from either patient tissue[30,31,33,34] or cell lines.[12-14,30,31] Direct comparisons of neoplastic cells to normal cell differentiation, however, must take into consideration properties of the malignant cells, such as aberrant gene expression and potential instability of phenotype during cell culture. In the present study, we analyzed primary cases and well-characterized cell lines which, collectively, span the phenotypic range of early T cell development.

Precursor T cell neoplasms presented here encompass a spectrum of intrathymic T cell development ranging from primitive cells, whose antigen receptor genes were retained in the germline configuration, to cells with rearranged and transcribed antigen receptor genes and a nearly mature T cell phenotype. Associated with developments in antigen receptor gene recombination and expression was the sequential appearance of T cell-associated markers. By analyzing each of these critical features in individual precursor T cell clones, we have begun to piece together the coordination of events in the T cell developmental process.

The earliest identifiable stage, analogous to the murine "prothymocyte,"[15] was surface expression of 3A1 (CD7), in association with either T1 or T11, in cells whose TCR genes were retained in the germline form. Neither T_β[33] nor T_γ gene rearrangements were demonstrable at this stage (cases 1 and 2) despite digestion with several restriction enzymes, and neither gene was apparently transcribed. Lack of nongermline T_α genes in these cases does not preclude the presence of T_α rearrangements because of the difficulty inherent in detection of gene rearrangements at this locus.[6,28,29] T_α gene rearrangement, however, in the absence of rearrangement of T_β and T_γ genes, is unprecedented, and absence of T_α mRNA suggests that T_α genes might not yet be rearranged in cases 1 and 2. Further indication of immaturity in cases 1 and 2 are the lack of expression of T6, the cortical thymocyte marker, and the absence of intracellular as well as surface T3. Alternatively, it could be argued that such primitive cells are not committed to T cell differentiation. These lymphoid cells show no evidence of B cell commitment, however, since they lack B cell markers,[33] have germline immunoglobulin genes,[33] and the 3A1+, T1+, and 3A1+, T11+ phenotypes are not found in B lineage neoplasms.[26,42]

T_β rearrangement occurs early in thymocyte differentiation and most precursor T cell neoplasms have similarly undergone such rearrangements.[43-46] Rearrangements may involve one or both alleles and, in one exceptional case reported here, trisomy of chromosome 7 apparently provided for rearrangement of three T_β and three T_γ alleles. In early stages, T_β transcripts are incomplete, and their 1.0-kb size results from a D-J-C transcript following D-J joining.[41] Case 3 in the current study is characterized by transcription of the 1.0-kb T_β mRNA without detectable complete (1.3 kb) transcripts. Its early thymocyte phenotype, 3A1+, T11−, T1+, T6+, cT3−, sT3−, and lack of T_α transcripts are indicative of an early differentiation stage. As with T_β, it is in this cell that we see the first evidence of T_γ gene rearrangement. Whether T_β and T_γ genes rearrange concurrently in human cells cannot be ascertained by this analysis but, based on findings reported here, rearrangements of both genes apparently occur as early events in T cell differentiation. It is noteworthy that T_β and T_γ genes were always simultaneously rearranged.

As a subsequent step, full-sized 1.3-kb T_β mRNA was detected. The "mature" T_β message was seen in all five cell lines and in cases 4 and 5. Provocatively, intracellular T3 was identified only when the 1.3-kb T_β mRNA was detected, a finding that suggests the possible existence of a common factor(s) that might regulate the coordinated expression of T_β and T3 genes. Intracellular T3 is known to appear early in thymocyte differentiation, prior to localization on the outer plasma membrane.[30]

Surface expression of T3 was identified only in cases in which T_α mRNA was detected. Two sizes of T_α mRNA, 1.5 and 1.3 kb, which likely represent complete and incomplete messages, respectively,[4] were detectable in both case 5 and Jurkat. Lack of expression of surface T3 in the absence of T_α transcription is consistent with obligatory production of a complete α-β heterodimer, which is noncovalently linked to the T3 complex for surface membrane T3 to appear.[8,11] Although T_γ mRNA was not observed in any of the leukemias analyzed, low abundancy message might not be demonstrable by use of a genomic J_γ probe. Further analysis with cDNA probes will be necessary to determine whether the T_γ

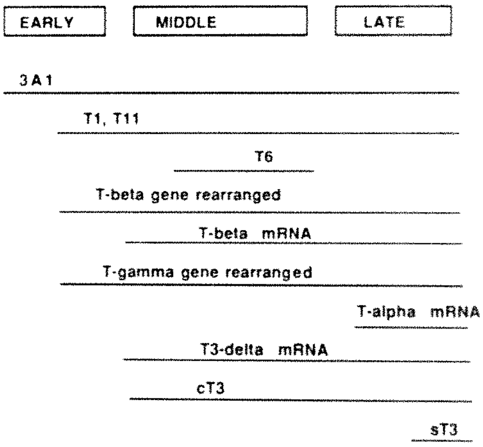

Fig 5. Hierarchy of T3/T cell receptor development. Precursor T cell neoplasms can be roughly segregated into three compartments—early, middle, and late. The phenotypic expression of cells within each compartment is shown along with the chronology of events beginning with rearrangement of T cell receptor genes and progressing to their transcription and, ultimately, to expression of the T3 molecular complex.

gene is transcriptionally active in these human pre-T neoplasms.

The picture that has emerged from the current analysis of precursor T cell neoplasms is a cascade beginning with 3A1 expression, followed by T1 and T11 expression, and T_β and T_γ gene rearrangement; T_β gene transcription, $T3_\delta$ gene transcription, and intracellular T3 accumulation; and, finally, T_α transcription and the appearance of surface T3 (Fig 5). In all, the elaboration of the antigen recognition function of T cells is shaped by regulated events within the thymus. It is tempting to speculate that regulation of antigen receptor development is mediated by surface molecules, such as 3A1, T1, and T11, which might serve as receptors for humoral or cellular factors present in the thymic microenvironment. In this regard, it is interesting to note that 3A1 appears on precursor cells, "prothymocytes," prior to entry into the thymus, and perithymic mesenchyme expresses a moiety detectable with antibody 3A1.[47] Analysis of the coordination of gene expression during T cell differentiation should provide leads into the identification of regulatory molecules.

ADDENDUM

The ordered hierarchy of rearrangement and expression of genes of the T cell receptor–T3 complex outlined in the present investigation is consistent with recently reported studies of murine fetal thymocytes[48] and human T cell leukemias.[49]

ACKNOWLEDGMENT

We thank Dr T. W. Mak for the T_α and T_β cDNAs, Dr C. Terhorst for T3 cDNA, and Dr T. W. Rabbitts for J_γ DNA. We are grateful to Dr J. Wang-Peng for cytogenetic analysis.

Identification of a Functional Role for Human Erythrocyte Sialoglycoproteins β and γ

By Marion E. Reid, Joel Anne Chasis, and Narla Mohandas

Four distinct erythrocyte membrane sialoglycoproteins (SGPs) denoted α, β, γ, and δ have been described, but their functions have not yet been defined. Recent evidence suggests that several of these SGPs associate with membrane skeletal proteins. Because the membrane skeletal protein network plays an important role in regulating the membrane material properties of deformability and mechanical stability, we wanted to determine whether the SGPs, through their interaction with the membrane skeleton, can modulate these membrane properties. We measured membrane mechanical stability and membrane deformability of erythrocytes that were deficient in either α, or δ or β and γ SGPs. Only erythrocytes deficient in β and γ SGP had altered membrane properties, as evidenced by marked decreases in both membrane mechanical stability (50% of normal) and membrane deformability (40% of normal). Erythrocytes deficient in either α or δ SGP had normal deformability and stability. Based on these data, we suggest that an interaction of β and/or γ SGP with the membrane skeleton plays a functionally important role in regulating normal erythrocyte membrane properties.

FOUR DISTINCT erythrocyte membrane sialoglycoproteins (SGPs) denoted α, β, γ and δ carrying different blood group specificities have been described,[1] but their role in regulating membrane function has not been defined. Recent evidence suggests that several of these SGPs associate with membrane skeletal proteins.[2-9] More specifically, both α and β SGP[5] have been shown to interact with protein 4.1, and the interaction between α SGP and protein 4.1 may be modulated by phosphoinositides.[3] Because the membrane skeletal protein network plays an important role in regulating the membrane material properties of deformability and stability, we wanted to determine whether SGPs, through their interaction with the membrane skeleton, can modulate these membrane properties. We measured mechanical stability and membrane deformability of erythrocytes that were deficient in either α or δ or β and γ SGPs. We found that only erythrocytes deficient in β and γ SGPs exhibited decreased mechanical stability and deformability, whereas erythrocytes deficient in either α or δ SGP had normal membrane mechanical properties. These data allow us to define a functionally important role for β and γ SGPs, that of regulating membrane properties of deformability and stability, possibly through their interaction with components of the skeletal protein network. The data further raise the possibility that membrane properties of other types of cells may be modulated by similar associations between cytoplasmic domains of transmembrane proteins and cytoskeletal elements.

MATERIALS AND METHODS

After informed consent was obtained from subjects with various SGP protein deficiencies, blood samples were drawn into acid citrate dextrose and analyzed within 30 hours of collection. SGP-deficient samples tested were from the following patients: E.P. for the α SGP deficiency, A.T. and R.W. for δ SGP deficiency and P.L., J.C., S.S., and T. L. for the β and γ SGP deficiencies.

Immunochemical and biochemical analysis. The absence of specific SGP was confirmed by immunochemical analysis of erythrocyte membranes. Preparation of erythrocyte membranes, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), periodic-acid Schiff's base (PAS) staining and immunoblotting were performed as described previously.[6,10] The monoclonal antibodies used for immunoblotting have been reported in detail.[6,11] In brief, LICR/R1.3 (R1.3) detects an epitope carried on the N terminus of both α and δ SGPs,[11] and NBTS/BRIC-10 (BRIC-10) recognizes an epitope on the N terminus of β SGP.[6] The polyacrylamide concentration was 3% for the stacking gel and 10% for the separating gel for PAS staining and Western immunoblotting and 3.5% to 17% nonlinear gradient gel for Coomassie brilliant blue staining.

The relative concentration of various membrane proteins was determined by the pyridine elution method previously described.[12] After destaining of Coomassie brilliant blue-stained SDS-PAGE gels, appropriate areas of gel corresponding to spectrin, band 3, protein 4.1, and actin were cut; the stain was eluted with pyridine and quantitated by measurement of absorbance at 605 nm. The relative concentration of skeletal protein was quantitated by determining the absorbance ratios of spectrin, protein 4.1, and actin to band 3.

To assess the state of spectrin self-association, nondenaturing PAGE was performed on spectrin extracted from normal and SGP-deficient membranes.[13,14] Spectrin was extracted by dialysis against hypotonic buffer (0.3 mmol/L of Na phosphate, 0.1 mmol/L of EDTA and 0.1 mmol/L of phenylmethylsulfonyl fluoride (PMSF) pH 8.0) at 4°C for 17 hours. The percentage of spectrin dimer (expressed as dimer/dimer plus tetramer) was determined by densitometric analysis of the nondenaturing gels.

Membrane deformability and mechanical stability measurements. Resealed membranes for deformability and stability measurements were prepared by a procedure adopted from Johnson.[15] Erythrocytes were washed three times in 5 mmol/L of Tris and 140 mmol/L of NaCl (pH 7.4). The erythrocytes were then lysed in 40 vol of 7 mmol/L of NaCl and 5 mmol/L of Tris (pH 7.4). The membranes were pelleted by centrifugation, resuspended in 10 vol of 5 mmol/L of Tris and 140 mmol/L of NaCl (pH 7.4), and incubated for 60 minutes at 37°C to promote resealing.

To measure membrane stability, 100 μL of resealed membranes pelleted by centrifugation was mixed with 3 mL of dextran (40,000

mol wt, 35 g/100 mL in 10 mmol/L of phosphate buffer, viscosity 95 centipoise, pH 7.4), and subjected to a continuous applied shear stress of 750 dynes/cm^2 in the ektacytometer.[16] Under this stress, the membranes progressively fragment, generating nondeformable spherical fragments. This process is detected as a time-dependent decrease in the deformability index (DI). The time required for the DI to fall to 50% of its maximum values is termed T_{50} and is a quantitative measure of membrane stability.[16]

The property of membrane deformability that determines the extent of membrane deformation that can be induced by a defined level of applied force was also measured by ektacytometry. For resealed membranes, the shear stress required to obtain a defined value of DI is determined by the property of membrane deformability, without contributions from either internal viscosity or cell volume.[17] A correlation exists between changes in deformability measured by this technique and those measured using the micropipette.[17] To measure this property, 30 μL of resealed ghosts were suspended in 3 mL of Stractan (22 cp viscosity, 290 mOsmol/kg, pH 7.4). The ghosts were then subjected to a linearly increasing shear stress in the ektacytometer. The DI was measured as a function of applied shear stress. When DI is plotted on a linear scale and the shear stress is plotted on a log scale, a linear relationship exists between these two variables for normal membranes. For membranes with decreased deformability, the linear relationship still exists; however, there is a parallel displacement of the lines to higher values of shear stress. From the differences in shear stress values required to obtain equivalent DIs, a value for relative membrane deformability is derived.[17,18]

RESULTS

Erythrocytes deficient in α or δ or β and γ SGPs were obtained from individuals who had previously been identified as lacking these SGPs.[6,19-21] The absence of specific SGP was confirmed by immunochemical analysis on erythrocytes from these donors. Figure 1 shows a representative example of each type of SGP deficiency. Coomassie brilliant blue staining of SDS polyacrylamide gradient gels showed that membranes deficient in α or δ or β and γ had the normal complement of skeletal proteins. PAS staining showed that membranes from E.P. were deficient in α SGP, membranes from A.T. were deficient in δ, and membranes from J.C. were deficient in β. Immunoblotting with R 1.3 (a monoclonal antibody that reacts with α and δ SGPs) showed that α and δ SGP-deficient erythrocytes lacked all bands corresponding to these SGPs, whereas control and β and γ-deficient erythroyctes had a normal complement of α and δ SGPs. Immunoblotting with another monoclonal antibody, BRIC-10 (an antibody with specificity for β SGP) showed that β SGP was absent only in β- and γ-deficient membranes and was present in normal amounts in control, α-deficient, and δ-deficient erythrocytes.

The two key, but distinct, membrane material properties, mechanical stability and deformability, are regulated by the skeletal proteins spectrin, actin, and protein 4.1 and their interactions.[12,22-28] Qualitative defects of spectrin and quantitative deficiencies of spectrin or protein 4.1 content were previously shown to result in marked decreases in membrane mechanical stability.[16] To define if deficiencies of various SGPs can also lead to altered membrane properties, the deformability and stability of resealed ghosts made from the SGP-deficient erythrocytes were measured using an ektacytometer.[16-18] In this system, resealed ghosts are exposed to a constant value of applied shear stress. The rate at which the deformability of resealed membranes decreases as a result of membrane fragmentation is used to quantitate membrane stability (Fig 2). The decrease in DI as a function of time for resealed membranes prepared from erythrocytes lacking either α or δ SGP was the same as that for control membranes, implying that these membranes had normal mechanical stability. On the other hand, membranes prepared from erythrocytes from all four individuals lacking β and γ SGPs fragmented at a much faster rate than normal

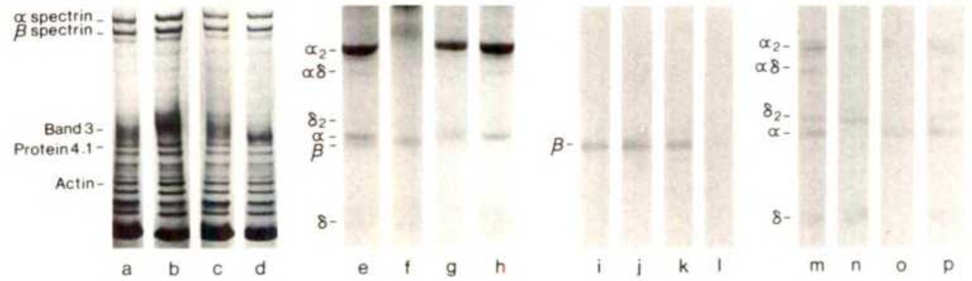

Fig 1. Immunochemical analysis of erythrocyte membranes. Coomassie brilliant blue-stained (lanes a through d), periodic-acid Schiff (PAS)-stained (lanes e through h), and Western blots (lanes i through p) of sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of sialoglycoprotein (SGP)-deficient membranes: results from a representative example of each type of SGP deficiency. Coomassie brilliant blue staining of SDS-polyacrylamide gradient gels showed that membranes deficient in α (lane b), δ (lane c), or β (lane d) had the normal complement (lane a) of skeletal proteins. The only observed difference between the various samples and control membranes was the decreased mobility of band 3 in the α-deficient membranes. This phenomenon has been described previously and is due to an increase in size of the *N*-glycosidically linked oligosaccharide on band 3.[41] The SGP components of these membrane preparations was determined following staining with PAS (lanes e through h). Membranes from E.P. were deficient in α SGP (lane f), membranes from A.T. were deficient in δ SGP (lane g), and membranes from J.C. were deficient in β SGP (lane h). The PAS-stained gel also illustrates the increased glycosylation of band 3 in the α-deficient membranes. Immunoblotting with antibody BRIC-10 showed that β SGP is absent only in β-deficient membranes (lane l). Normal complement of β SGP is present in control membranes (lane i) and membranes from erythrocytes lacking α or δ SGP (lanes j and k). Immunoblotting with the R1.3 shows that α SGP-deficient erythrocytes lack bands corresponding to monomeric α, dimeric α, and the heterodimer of α and δ (lane n). Membranes from erythrocytes deficient in δ SGP lack monomeric δ, dimeric δ, and the heterodimer of α and δ (lane o). The α and δ SGP content was normal in control erythrocytes (lane m) and in the β-deficient erythrocytes (lane p).

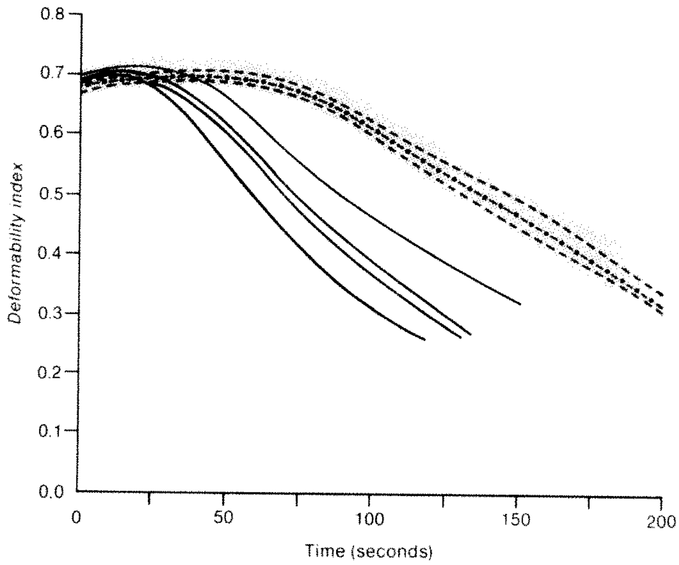

Fig 2. Membrane stability of sialoglycoprotein (SGP)-deficient erythrocytes. The deformability index of erythrocyte membranes deficient in β and γ SGPs decreased more rapidly with time when exposed to constant shear stress (—) when compared with normal erythrocyte membranes (shaded area), implying decreased mechanical stability. In contrast, the rate of decline of deformability index of erythrocyte membranes deficient in α SGP (- - -) and δ SGP (---) was normal, implying that these membranes had normal mechanical stability. α SGP-deficient membranes were tested on three different occasions and yielded similar results.

membranes. The mechanical stability of these membranes was only 50% of normal (range 42% to 62%).

The property of membrane deformability determines the extent of membrane deformation that can be induced by a defined level of applied force. A value for relative membrane deformability of erythrocytes is derived by comparing the values of applied shear stress required in the ektacytometer to obtain equivalent membrane deformation for various resealed ghost preparations. As shown in Fig 3, membranes that lacked α or δ SGP underwent the same extent of membrane deformation as did control membranes at equivalent values of applied shear stress. This implies that in addition to having normal mechanical stability, these membranes were also normally deformable. In contrast, membranes lacking β and γ SGPs required higher levels of applied shear stress than did control membranes to reach equivalent membrane deformation, implying that these membranes have decreased membrane deformability. The membrane deformability of β-deficient and γ SGP-deficient erythrocytes from the four individuals was, on the average, only 40% of normal (range 27% to 46%).

In addition to these alterations in membrane properties, the β and γ SGP-deficient erythrocytes were elliptocytic, an abnormality that has been described previously.[6,21] In con-

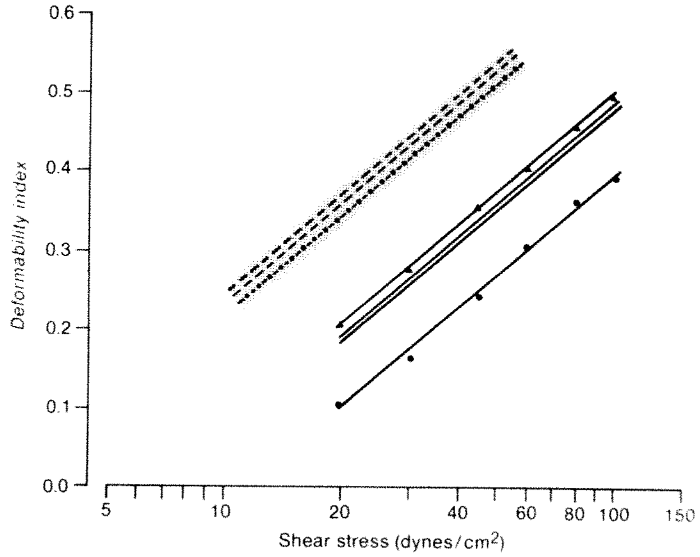

Fig 3. Membrane deformability of sialoglycoprotein (SGP)-deficient erythrocytes. Erythrocyte membranes deficient in β and γ SGPs required significantly higher values of applied shear stress (—) as compared with normal membranes (shaded area) to reach equivalent deformation. The lines are parallel; thus, β and γ SGP-deficient membranes required 2.5-fold higher shear stress than did normal membranes to reach equivalent deformation at all points along the curve, indicating that the membranes had 0.4 times normal deformability. In contrast, α SGP-deficient (-.-) and δ SGP-deficient (---) membranes required the same shear stress as normal membranes to reach equivalent deformation, implying normal membrane deformability. α SGP-deficient membranes were tested on three different occasions and yielded similar results.

trast, erythrocytes lacking α or δ or both α and δ had normal discoid morphology.[29,30] Decreased membrane stability and deformability in conjunction with elliptocytic morphology have previously been documented in hereditary elliptocytosis as a consequence of primary skeletal protein defects. In these cases, defective oligomerization of spectrin resulting from qualitative defects in α-spectrin, as well as protein 4.1 deficiency have been identified as responsible for the membrane abnormalities.[26,27,31,32] To rule out the possibility that similar skeletal protein abnormalities were involved in the altered properties of the β and γ SGP-deficient erythrocytes, we measured the spectrin and protein 4.1 content of these membranes as well as the state of spectrin oligomerization in the membrane. The ratios of both spectrin and protein 4.1 to band 3 were normal (spectrin to band 3, 0.95-1.05, and protein 4.1 to band 3, 0.9-1.05). In addition, the ratio of spectrin dimers to dimers plus tetramers in the membranes from two unrelated β and γ SGP-deficient individuals was within normal limits (P.L. 3.5%, S.S. 4.4%, normal range 2.0% to 5.4%), a result consistent with normal spectrin self-association.[13,14] Thus, the membrane and morphological abnormalities we describe are primarily due to the SGP deficiency and not to any of the skeletal protein alterations previously identified.

DISCUSSION

The data from the present study allow us to define an important functional role for SGP β and γ in erythrocytes, that of regulating membrane physical properties. Because deformability and stability are largely determined by the membrane skeleton, the data further imply that regulation of membrane properties by SGP β and γ may occur through the interaction of these SGPs with the membrane skeletal network. Experimental evidence to support such an interaction has been previously reported by several investigators[4,5,7,8] and, more specifically, it appears that SGP β interacts with the protein 4.1 component of the membrane skeleton.[4,5] In vitro studies have also shown interaction between SGP α and protein 4.1,[2,3,9] but this interaction does not appear to regulate either membrane deformability or stability since erythrocytes deficient in this major SGP have normal membrane properties. This raises the possibility that although SGP α has the potential to interact with protein 4.1, this interaction may not occur in normal erythrocyte membranes. Support for such a suggestion comes from recent experimental evidence which has shown that although SGP α can be removed readily and totally from normal membranes by detergent extraction, binding of specific ligands to SGP α induces the association of this SGP with the membrane skeleton and a concomitant decrease in membrane deformability.[33] Thus, it appears that while SGP β is normally associated with the membrane skeleton and plays a physiologically important role in regulating membrane properties, the interaction of SGP α with skeletal proteins is regulated by ligand binding or by changes in phospholipid metabolism.[3,33]

β and γ SGP-deficient erythroyctes were previously reported to be resistant to invasion by *Plasmodium falciparum*.[34] The present data suggest that the decreased membrane deformability that we identified may play a role in this resistance. Precedence for this suggestion is indicated by the close relationship between decreased membrane deformability and decreased malarial parasite invasion previously documented in ovalocytes.[35,36]

The state of spectrin self-association and spectrin–actin–protein 4.1 interaction were previously shown to play a key role in regulating membrane mechanical stability.[26,27,31,32] Decreased membrane stability in conjunction with elliptocytic morphology has previously been documented in hereditary elliptocytosis due to primary skeletal protein defects that affect these two protein associations. Defective spectrin oligomerization as a result of a number of qualitative defects in α-spectrin, as well as quantitative protein 4.1 deficiency are the two common causes of decreased membrane stability. Our finding of the normal state of spectrin oligomerization and normal membrane content of protein 4.1 rule out the possibility that the decreased membrane stability of β and γ SGP-deficient cells could have resulted from primary skeletal protein defects. What is more important, these data allow us to identify yet another membrane protein association important in regulating membrane mechanical properties, the association of the cytoplasmic domain of a transmembrane protein with skeletal proteins. Because proteins analogous to erythrocyte protein 4.1 have been identified in various nonerythroid cells,[37-40] the present findings raise the possibility that the membrane physical properties of these cells may also be regulated by similar association between cytoplasmic domains of transmembrane proteins and components of the membrane skeleton.

ACKNOWLEDGMENT

We are grateful to the staff of the reference laboratory of the Irwin Memorial Blood Bank of the San Francisco Medical Society for supplying the α-deficient erythrocytes and to the staff and donors from the blood bank of the Alameda-Contra Costa Medical Association for supplying the δ-deficient blood samples. We thank S. Lee and P. A. Stiles from the consultation services from Ortho Diagnostics, Canada division for helping to procure the β- and γ- blood samples and P. Colpitts from the Regional Laboratories of the Moncton Hospital for supplying β- and γ-deficient erythrocytes. We thank D. J. Anstee for making the monoclonal antibodies available and for being instrumental in making certain blood samples accessible. One of us (M.R.) is indebted to him for his invaluable guidance and support. We also thank T. Iarocci for performing the spectrin analysis, M. Roitsheyn, J. Reeves, and M. Rossi for excellent technical assistance, and J. Harris for his expert assistance in preparing the manuscript.

Studies on the Ultrastructure of Fibrin Lacking Fibrinopeptide B (β-Fibrin)

By M.W. Mosesson, J.P. DiOrio, M.F. Müller,* J.R. Shainoff,† K.R. Siebenlist, D.L. Amrani,
G.A. Homandberg, J. Soria,‡ C. Soria,§ and M. Samama‡

Release of fibrinopeptide B from fibrinogen by copperhead venom procoagulant enzyme results in a form of fibrin (β-fibrin) with weaker self-aggregation characteristics than the normal product (αβ-fibrin) produced by release of fibrinopeptides A (FPA) and B (FPB) by thrombin. We investigated the ultrastructure of these two types of fibrin as well as that of β-fibrin prepared from fibrinogen Metz (Aα16 Arg→Cys), a homozygous dysfibrinogenemic mutant that does not release FPA. At 14°C and physiologic solvent conditions (0.15 mol/L of NaCl, 0.015 mol/L of Tris buffer pH 7.4), the turbidity (350 nm) of rapidly polymerizing αβ-fibrin (thrombin 1 to 2 U/mL) plateaued in <6 min and formed a "coarse" matrix consisting of anastomosing fiber bundles (mean diameter 92 nm). More slowly polymerizing αβ-fibrin (thrombin 0.01 and 0.001 U/mL) surpassed this turbidity after ≥60 minutes and concomitantly developed a network of thicker fiber bundles (mean diameters 118 and 186 nm, respectively). Such matrices also contained networks of highly branched, twisting, "fine" fibrils (fiber diameters 7 to 30 nm) that are usually characteristic of matrices formed at high ionic strength and pH. Slowly polymerizing β-fibrin, like slowly polymerizing αβ-fibrin, displayed considerable quantities of fine matrix in addition to an underlying thick cable network (mean fiber diameter 135 nm), whereas rapidly polymerizing β-fibrin monomer was comprised almost exclusively of wide, poorly anastomosed, striated cables (mean diameter 212 nm). Metz β-fibrin clots were more fragile than those of normal β-fibrin and were comprised almost entirely of a fine network. Metz fibrin could be induced, however, to form thick fiber bundles (mean diameter 76 nm) in the presence of albumin at a concentration (500 μmol/L) in the physiologic range and resembled a Metz plasma fibrin clot in that regard. The diminished capacity of Metz β-fibrin to form thick fiber bundles may be due to impaired use or occupancy of a polymerization site exposed by FPB release. Our results indicate that twisting fibrils are an inherent structural feature of all forms of assembling fibrin, and suggest that mature β-fibrin or αβ-fibrin clots develop from networks of thin fibrils that have the ability to coalesce to form thicker fiber bundles.

© 1987 by Grune & Stratton, Inc.

THROMBIN-CATALYZED fibrin formation begins with the release of fibrinopeptide A (FPA) from the amino terminus of the Aα chains of fibrinogen[1-5] and is accompanied by the slower release of fibrinopeptide B (FPB) from Bβ chains. Reptilase, a snake venom enzyme from *Bothrops atrox*, removes only FPA,[6-8] release of which is sufficient for fibrin polymerization (α-fibrin) to occur.[7-9]

Mature fibrin clots evidently assemble from a network of thin protofibrils that subsequently, under physiologic solvent conditions, undergo lateral aggregation, causing increased fiber thickness.[10-12] Since 1947, two extreme forms of three-dimensional fibrin networks, namely "fine" and "coarse," have been recognized.[13] The fine gel structure can be produced at high ionic strength and pH, is translucent and friable, and consists of a network of thin, highly branched, twisting fibers.[14] The coarse gel structure, which forms at or below physiologic ionic strength and pH, is opaque and easily synerized. Owing to a strong tendency for lateral association under such conditions, these matrices are characterized by thick fiber bundles, the thicknesses of which are reflected by turbidity measurements[10-13,15-18] and determined in part by the kinetics of fiber growth.[11,12,18,19] That is, slowly forming clots at physiologic pH and ionic strength tend to develop thicker fiber bundles than do more rapidly forming clots.[12,18,20]

Some investigators[2,3,5,8,21] have suggested that FPB release is essential for lateral fiber growth. Other studies, however, indicate that this is not the case,[10,11,16,22,23] since reptilase cleavage of FPA to form α-fibrin results in a coarse matrix whose cables are only moderately narrower than those formed by αβ-fibrin.[10,11,22] The light scattering studies of Müller and co-workers[24] also indicated that α-fibrin and αβ-fibrin were similar with respect to branching tendency and lateral aggregation. Thus, although FPB release is not strictly required for gelation or for lateral aggregation, its release may increase the rate and extent of lateral associations.[10,11,16] In additon, fiber slippage is reduced, fiber stiffness is increased, and branch points in αβ-fibrin fibers are probably reinforced by noncovalent bonding correlating with FPB release.[14,23,25] Mihalyi and Donovan[26] recently provided calorimetric data indicating that noncovalent interactions of the fibrin(ogen) D domains are enhanced by removal of FPB.

Preferential release of fibrinopeptide B by copperhead venom procoagulant enzyme (CVE)[27] is sufficient to cause normal fibrinogen to polymerize.[28,29] Based on their gross appearance, these clots tend to be fine at temperatures

<25°C and are readily dissociated at 37°C.[28,29] Judging from light scattering measurements on fibrin clots formed at 20°C and 37°C, it apears that selective cleavage of FPB at low enzyme concentrations results in the highest branching density and the lowest degree of lateral aggregation.[24]

In this study, we used electron microscopy to investigate the three-dimensional structure of β-fibrin formed from normal fibrinogen and from the homozygous congenital fibrinogen abnormality known as fibrinogen Metz (Aα Arg 16 → Cys).[30-32] To preserve the structures of these fragile fibrin clots, we prepared our material using the critical point drying technique[33] as recently used for the study of fine fibrin matrices.[14]

MATERIALS AND METHODS

Normal fibrinogen fraction I-2 (>95% coagulable) and fibrinogen Metz fraction I-2 were purified from citrated plasma by the method of Blombäck and Blombäck.[34] In some experiments, chromatographically purified normal peak 1 fibrinogen[35] was used. As assessed by the position of the fibrinogen band in $NaDodSO_4$-polyacrylamide gel electrophoresis (PAGE) (5% acrylamide),[36,37] unreduced fibrinogen Metz molecules were devoid of polymeric forms and the preparation was ~95% pure.

Sulfhydryl titrations of various fibrinogen preparations were carried out either with Ellman's reagent, 5,5′-dithiobis (2-nitrobenzoic acid) (DTNB),[38] or with ^{3}H- or ^{14}C-iodoacetic acid (specific activities 140 mCi/mmol and 11.1 mCi/mmol, respectively). After reaction with the iodoacetate, samples were extensively dialyzed, dissolved in 10 mL of Aquasol-2 liquid scintillation cocktail (New England Nuclear, Boston), and radioactivity was subsequently determined in a Packard model 2425 spectrometer.

Freeze-dried human thrombin (H-1), a gift from Dr D. L. Aronson, was reconstituted in H_2O and stored frozen at a concentration of 100 U/mL. CVE was prepared as described by Herzig and co-workers[27] and had an activity of 33 TAME (Nα-p-tosyl-L-arginine methyl ester) U/mL. Common chemicals were of reagent grade.

Fibrinogen samples for fibrinopeptide analyses were brought to a final concentration of 5 mg/mL in a buffer of 0.15 mol/L NaCl, 0.01 mol/L of Tris pH 7.2 ± 0.1, and incubated in small glass tubes after the addition of thrombin or CVE. Release of FPA and/or FPB from fibrinogen was measured after overnight incubation using the high-performance liquid chromatography (HPLC) chromatographic system described by Kehl and Henschen.[39] Specifically, the fibrinopeptides were analyzed with a Varian model 5040 HPLC apparatus on an Ultrasil ODS reverse-phase column (25 cm × 4.6 mm) (Rainin Instrument, Woburn, MA) using a linear gradient of acetonitrile (12% to 28%) buffered with 25 mmol/L of ammonium acetate pH 6.0.

αβ-Fibrin or β-fibrin was prepared by addition of thrombin or CVE (0.66 or 0.13 U/mL), respectively, at 14 ± 1°C, to normal fibrinogen, followed by overnight incubation at 14°C. Metz β-fibrin was generated at 14°C or 37°C by addition of CVE (0.66 U/mL) or thrombin (1 to 5 U/mL). In some cases, bovine serum albumin (BSA) (500 μmol/L, final concentration; Sigma Chemical, St Louis) or $CaCl_2$ (5 mmol/L), or both were included in the clotting mixture.

HPLC determination of fibrinopeptides released from normal β-fibrin under these conditions revealed the expected presence of FPB and des-Arg FPB and ≤10% of the potentially available amount of FPA. Metz β-fibrin showed only FPB and des-Arg FPB. For those batches of CVE that contained Aα chain degradative activity, tosyl lysine chloromethyl ketone (Sigma Chemical) 10^{-4} mol/L, final concentration, was added to the clotting mixture prior to CVE addition to block this activity. Turbidity measurements at 350 nm on fibrin clots were carried out at 14 ± 1°C in a Gilford model 240 spectrophotometer equipped with a jacketed specimen holder.

Certain β-fibrin specimens were subjected to gel-sieving chromatography at 37°C to separate β-fibrin from a minor αβ-fibrin contaminant.[29] In brief, following the incubation period with CVE, the clot was overlaid with 1 mmol/L of phenylmethylsufonylfluoride (PMSF) in buffer and incubated in the presence of this reagent for at least 2 hours. The fibrin was then dissociated by being warmed to 37°C, mixed with an equal volume of 0.3 mol/L of NaCl, 0.03 mol/L of Tris buffer pH 7.4 ± 0.1 PMSF 10^{-4} mol/L, and gel-filtered at 37°C through a Sepharose 2B column equilibrated in this same buffer. Early eluting fractions containing the αβ-fibrin contaminant were discarded, whereas fractions containing "β-fibrin monomer" eluting at a concentration above six-tenths of the β-fibrin peak height were pooled and stored frozen at −30°C at concentrations ranging from 400 to 800 μg/mL. For electron microscopy or turbidity measurements, aliquots of β-fibrin monomer were thawed at 37°C for 30 minutes, diluted 1:1 with H_2O, and then incubated at 14°C for the desired amount of time. Preparations were monitored by $NaDodSO_4$-PAGE[36,37] to verify whether anticipated fibrinopeptide cleavages had occurred and to determine if other proteolytic attack had occurred (eg, on Aα chains).

Samples of purified fibrin for negative staining electron microscopy were formed at 14 ± 1°C as 50-μL drops (50 to 500 μg/mL) in a Petri dish that had been humidified with a moist sponge, incubated for 16 to 18 hours with thrombin or CVE, picked up on glow-discharged carbon films, and then negatively contrasted with 2% (wt/vol) uranyl sulfate. For processing by the critical point drying technique, clots were picked up on glow-discharged carbon-coated 200-mesh copper grids, fixed with glutaraldehyde (2.5%, vol/vol) in 0.1 mol/L of HEPES buffer pH 7.0, containing 0.2% (wt/vol) tannic acid, washed several times with H_2O, stained with 0.5% (wt/vol) uranyl acetate, and washed again with H_2O.[14] The specimen was then dehydrated in graded ethanol solutions (20% to 100%, vol/vol) and CO_2 critical point dried[33] using a Tousimis model 780A critical point drying apparatus (Tousimis Scientific Instruments, Rockville, MD).

Plasma fibrin clots were prepared from blood that had been drawn into a plastic syringe, immediately transferred to a centrifuge tube, and then centrifuged at 3,000 g for 3 to 5 minutes to remove cellular elements. The supernatant plasma was incubated overnight at room temperature, and the resulting clot was synerized, washed extensively with saline, and fixed overnight at 4°C in 2% (wt/vol) glutaraldehyde solution in 0.1 mol/L of phosphate buffer pH 7.2. Metz fibrin clots were also prepared without syneresis from purified Metz fibrinogen at 2 mg/mL. The fixed preparation was incubated for 90 minutes with 2% osmium tetroxide in 0.1 mol/L of phosphate buffer, dehydrated in graded ethanol solutions, and embedded in Spurr's low-viscosity medium.[40] Thin sections were prepared using a diamond knife and a Reichert Ultracut ultramicrotome and stained with 5% aqueous uranyl acetate and Sato's lead citrate solution.[41]

Electron microscopy was performed with a Philips model 400 transmission electron microscope at 60 to 120 kV or with the University of Wisconsin high-voltage (1,000 kV) electron microscope at Madison, WI. Stereo images were made at magnifications of 5,000x to 22,000x at tilt angles of 3° to 6°.

RESULTS

We prepared β-fibrin at 14°C to minimize cleavage of FPA by CVE,[28] and we used this same temperature for polymerization of other forms of fibrin. The standard way of processing fibrin for transmission electron microscopy (TEM) is to pick up a clot sample by passing a carbon-coated grid through a fibrin clot. The grid surface is washed subsequently with buffer and uranyl sulfate and then air dried. Samples processed in this way have been suitable for observing the structure of a normal coarse fibrin matrix[42,43] and for characterizing the structure of certain abnormal fibrins such as fibrinogen Paris I.[44] The Metz clot structure and that of β-fibrin was so fragile, however, that at best we found discontinuous short strands and occasionally anastomosing fiber bundles and thin fibrils adherent to the underlying substrate. To preserve the three-dimensional structure of this type of clot, we processed the sample using the critical point drying procedure.[33] This technique has been used for demonstrating previously unrecognized features of fine clot matrices.

αβ-Fibrin. Images of critical point dried, rapidly polymerizing αβ-fibrin (thrombin, 1 U/mL) formed at 14°C under physiologic conditions (ie, I ~0.15, pH 7.4), revealed a coarse matrix consisting predominantly of twisted anastomosing cables (Fig 1A, Table 1). These cables showed typical cross-striations (~22 nm period) when viewed at a higher magnification than that shown in Fig 1 (data not shown).*

At a 100-fold lower thrombin concentration (0.01 U/mL), the rate of fibrin polymerization was considerably slowed (Fig 3); nevertheless, the clot ultimately developed considerably greater turbidity than fibrin formed at 1 U/mL. These observations confirm studies indicating that slow rates of fibrin polymerization favor higher degrees of lateral aggregation (ie, thicker fiber bundles).[12,18,20] At a thrombin concentration of 0.001 U/mL, clot development proceeded even less rapidly than at 0.01 U/mL although the turbidity eventually exceeded that of rapidly polymerizing αβ-fibrin. NaDodSO$_4$-PAGE analysis of fibrin specimens taken at the time of fixation for critical point drying, indicated that complete FPA release had occurred in all cases, but that in the specimen prepared at a thrombin concentration of 0.001/mL, only 50% of FPB had been released.

Consistent with turbidity measurements, fibrin formed at 0.01 U/mL or 0.001 U/mL revealed a network predominantly composed of large anastomosing fiber bundles that tended to be thicker than those from rapidly polymerized αβ-fibrin (Fig 1). In addition to the thick cable network, however, there was also a prominent network of thinner fibrils. This second type of matrix was most prominent at the lowest thrombin concentration (0.001 U/mL) and consisted of highly branched, twisting fibrils (Fig 4) that appeared to entrap and merge with large fiber bundles. The thick cables forming under this latter condition were composed of loosely packed fibrils (arrows, Fig 1C) and did not display the striations typical of more tightly packed bundles.

β-Fibrin. β-Fibrin gels formed at 14°C can be dissociated by being warmed to 37°C, and the resulting β-fibrin monomer can subsequently be polymerized by incubation at room temperature or below.[28,29] This process can be carried out repeatedly on material that has been inactivated with PMSF. Turbidity measurements on such a β-fibrin monomer preparation (Fig. 5) indicated that the onset of polymeriza-

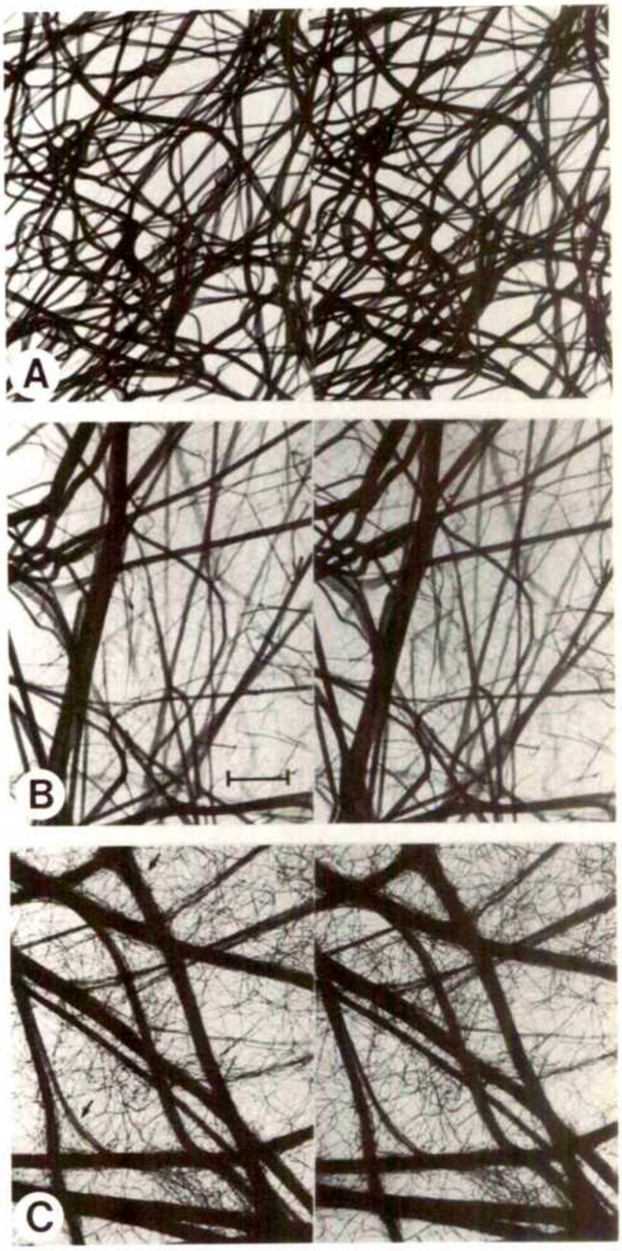

Fig 1. Stereo images by transmission electron microscopy (TEM) of αβ-fibrin (500 μg/mL) prepared by incubation overnight at 14°C under "coarse clot" buffer conditions (0.15 mol/L of NaCl, 0.015 mol/L of Tris buffer, pH 7.4) at the following thrombin concentrations: (A) 1 U/mL; (B) 0.01 U/mL; (C) 0.001 U/mL. Bar = 1,000 nm. The arrows in (C) indicate loosely packed fiber bundles.

---

*Beam penetration of the thick fiber bundles that form in rapidly polymerizing α,β-fibrin or other densely packed fibers at relatively low magnification (eg, 10,000×) is poor using TEM even at 120 kV. Striations are readily observed in thin sections of such fibers, (eg, Fig 2A), in critical point dried specimens at higher magnification (eg, 20,000×), or using higher voltages (eg, high-voltage electron microscopy, HVEM).

Table 1. Fiber Diameter of Thick Fiber Bundles of $\alpha\beta$-Fibrin and β-Fibrin

Preparation	Concentration (μg/mL)	n*	Fiber Diameter (nm) Mean	SD	Range
$\alpha\beta$-Fibrin (thrombin, 2 U/mL)	50	36	83	±37	50–170
$\alpha\beta$-Fibrin (thrombin, 1 U/mL)	500†	89	92	±39	36–260
$\alpha\beta$-Fibrin (thrombin, 0.01 U/mL)	500	43	118	±59	35–256
$\alpha\beta$-Fibrin (thrombin, 0.001 U/mL)	500	36	186	±90	60–536
β-Fibrin monomer	355	55	212	±80	40–520
β-Fibrin (CVE, 0.66 U/mL)	500	36	87	±30	35–170
β-Fibrin (CVE, 0.13 U/mL)	500	48	135	±73	35–421
Metz β-fibrin + albumin + Ca^{2+}	500	29	76	±32	39–194

In matrices containing significant amounts of both "fine" and "coarse" networks, there appeared to be no sharp size transitions in the progression from thin fibers in the fine matrix (7 to 30 nm in diameter) toward thicker fibers approaching the mean values. For purposes of this analysis, we defined the diameter of a coarse fiber bundle as ≥35 nm.

*Number of fibers measured.

†Owing to the thickness of the clot in the critical point dried specimen, it seemed tenuous to assume that areas selected for fiber measurement were representative of the fiber population in the clot. For that reason, we also prepared thin sections of an imbedded specimen under these same conditions. The fiber diameter determined from this type of specimen preparation was 92 ± 26 nm, range 37–150 nm. SD and range of values were lower because we used only the minimum cross-sectional diameter of any given fiber to avoid including measurement of tangential or oblique sections of fibers in our calculations.

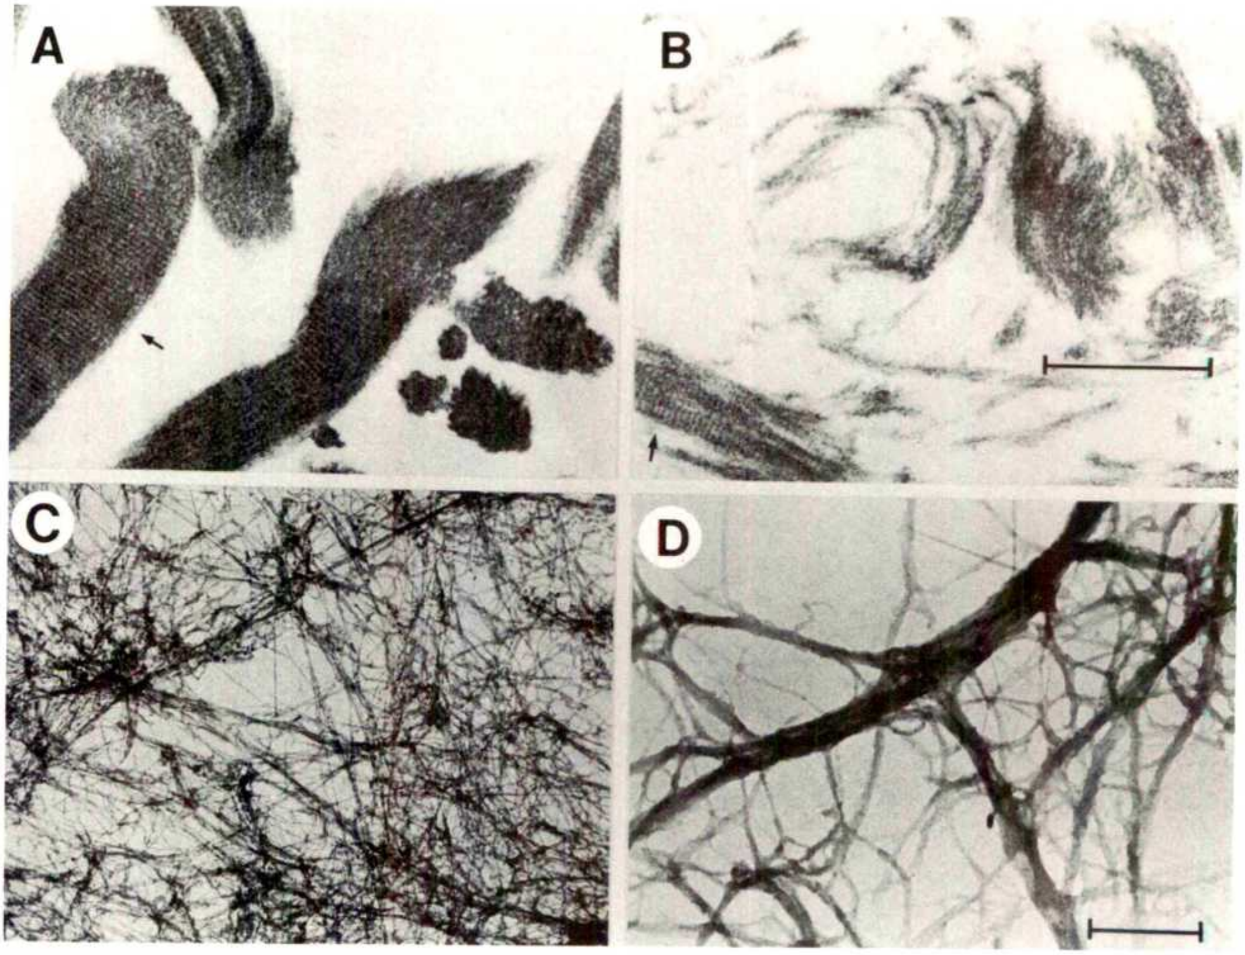

Fig 2. Comparison of the ultrastructure of a Metz plasma fibrin clot with Metz fibrin formed in the presence of albumin or Ca^{2+} or both (TEM). (A) Thin section of a normal plasma fibrin clot; (B) thin section of a Metz plasma clot; bar = 500 nm (A and B); (C) critical point dried specimen of Metz fibrin prepared in the presence of 5 mmol/L of $CaCl_2$; (D) critical point dried specimen of Metz fibrin prepared with albumin 500 μmol/L and $CaCl_2$ 5 mmol/L; bar = 500 nm (A and B). Arrows (A and B) point to periodic striations that occur in thick fiber bundles.

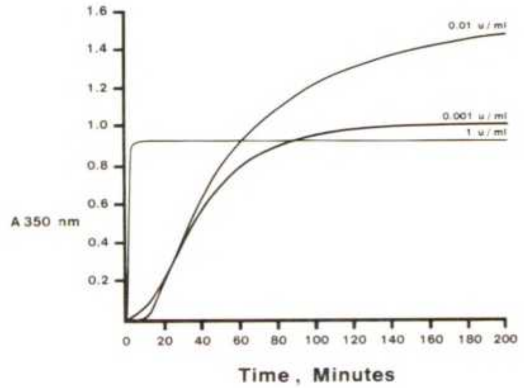

Fig 3. Turbidity measurements on $\alpha\beta$-fibrin. These experiments were carried out under the same conditions described in Fig 1. Thrombin was added to a final concentration of 1 U/mL, 0.01 U/mL, or 0.001 U/mL; absorbance (A_{350} nm) was monitored as a function of time.

tion was more rapid than that of β-fibrin formed by direct addition of CVE (Fig 6). The initial rate of turbidity rise of β-fibrin forming at the higher CVE concentration (0.66 U/mL), however, was about the same as the value for β-fibrin monomer extrapolated to a concentration of 500 μg/mL (ie, 0.061/min *v* 0.065/min). Electron micrographs of the β-fibrin monomer clot showed a network of twisting, occasionally anastomosing cables (Fig 7A). The mean fiber diameter was greater than in any other type of β-fibrin or αβ-fibrin matrix (Table 1).

β-Fibrin produced by addition of CVE (Fig 7) formed a network of thick cables frequently displaying periodic striations (see footnote, page 1075) typical of α-fibrin or αβ-fibrin bundles. The fiber bundles in these networks, like the β-fibrin monomer network, anastomosed only occasionally relative to αβ-fibrin clots. At the highest CVE level (0.66 U/mL), the matrix revealed occasional areas of fine, fibrillar networks, usually bridging between thick cables (Fig 7B) or appearing to represent an unraveled or frayed portion of a thick fiber bundle. At a lower CVE level (0.13 U/mL), fiber bundles in the matrix were more loosely packed (Fig 7C, arrow) and wider than those formed at the higher CVE concentration. In addition to the predominant thick cable structure, this clot showed a considerable network of fine twisting fibrils (Fig 7C and Fig 4B).

Metz β-fibrin. Metz β-fibrin is more transparent, less viscous, and more easily disrupted than normal β-fibrin. In contrast to normal, Metz β-fibrin formed by direct addition of thrombin or CVE at 14°C or that formed at 14°C from Metz β-fibrin monomer solutions (ie, first incubated with thrombin at 37°C), revealed a matrix comprised almost entirely of thin, twisting, and highly branched fibrils (Figs 4C and 7D) that occasionally coalesced to form somewhat thicker, relatively short, uneven bundles. These observations are consistent with the very low turbidity recorded at 350 nm (Fig 6).

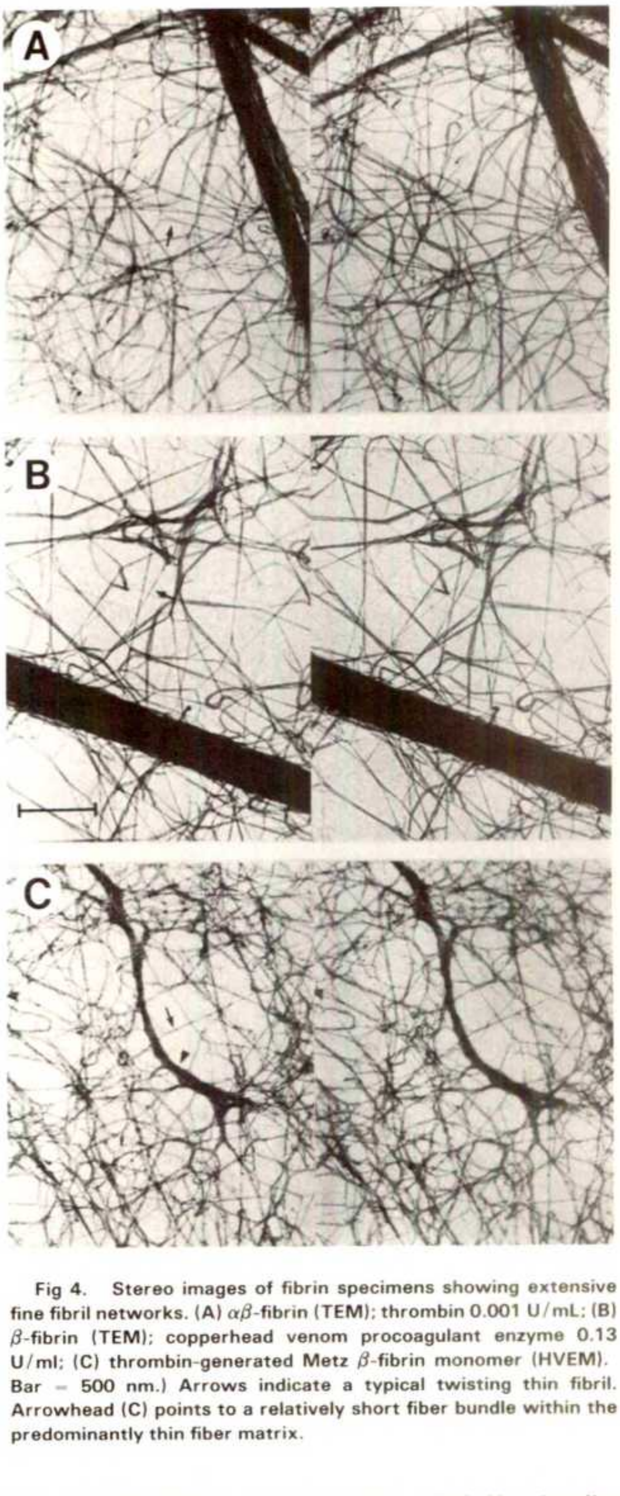

Fig 4. Stereo images of fibrin specimens showing extensive fine fibril networks. (A) αβ-fibrin (TEM); thrombin 0.001 U/mL; (B) β-fibrin (TEM); copperhead venom procoagulant enzyme 0.13 U/ml; (C) thrombin-generated Metz β-fibrin monomer (HVEM). Bar = 500 nm.) Arrows indicate a typical twisting thin fibril. Arrowhead (C) points to a relatively short fiber bundle within the predominantly thin fiber matrix.

To evaluate the type of Metz fibrin matrix formed in vivo, we prepared fibrin directly from native plasma and examined thin sections by electron microscopy (Fig 2). Normal fibrin yielded the expected thick, striated cables (Fig 2A, arrow), whereas Metz fibrin yielded loosely packed fiber bundles that frequently were sufficiently in register to yield a striated pattern (Fig 2B, arrow). Fibrin aggregation is well known to accelerate in plasma,[45] and this is due in part to effects related to the presence of albumin and IgG.[46,47] The accelerating effect is also accompanied by increased clot turbidity that is attributable, at least in part, to the presence of albumin or IgG, or both,[47] and Ca^{2+}.[48,49] To provide an explanation for the more mature structure of Metz plasma

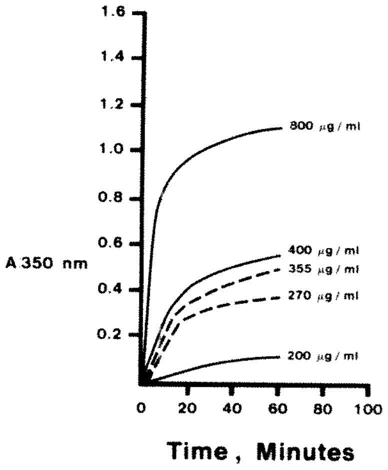

Fig 5. Turbidity measurements on β-fibrin monomer. Repolymerization at 14°C under standard buffer conditions of β-fibrin monomer that had been dissociated at 37°C (—) or further processed after dissociation at 37°C by molecular exclusion chromatography to remove $\alpha\beta$-fibrin contamination (---). The curves developed by chromatographically processed β-fibrin monomer are in register with those of unprocessed β-fibrin monomer, suggesting that a small amount of $\alpha\beta$-fibrin contamination does not materially change the structure of the matrix that forms.

fibrin relative to purified thrombin-generated or CVE-generated Metz fibrin, we attempted to induce thick fibril formation by allowing thrombin-generated Metz fibrin to polymerize in the presence of albumin (500 μmol/L) or 5 mmol/L of $CaCl_2$, or both (Fig 6). Measurements in the presence of albumin showed increased turbidity developing slowly over several hours; this effect was even more marked when 5 mmol/L of $CaCl_2$ was also present, although addition of $CaCl_2$ alone to Metz fibrin had little effect (Figs 6 and 2C). Examination and measurement of critical point dried fibrin specimens confirmed that increased thick bundle formation had occurred in albumin-containing specimens (cf Fig 2C and 2D). The thick bundles, like the fine fibrils, had a tendency to twist, but periodic striations were not observed. As assessed by TEM of thin sections, thick fiber bundle formation could also be induced in Metz β-fibrin formed at a concentration approximating that in plasma (ie, 2 mg/mL) (data not shown).

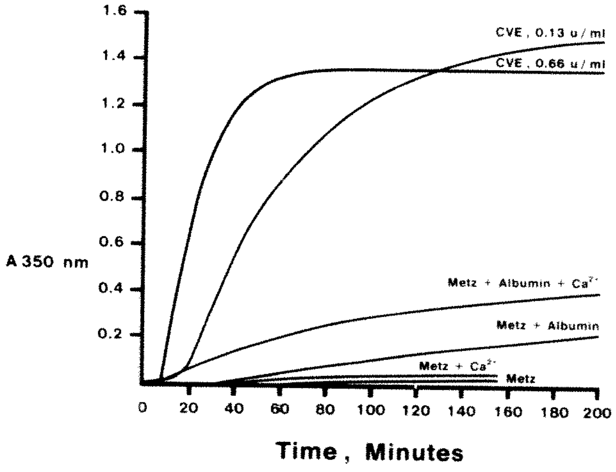

Fig 6. Turbidity measurements on β-fibrin (500 μg/mL). CVE additions, 0.66 or 0.13 U/mL, to normal fibrinogen at 14°C were made under the same buffer conditions described in Fig 1. Metz β-fibrin was incubated with thrombin (5 U/mL) at 14°C and allowed to polymerize under the following conditions: Metz + buffer; Metz + $CaCl_2$, 5 mmol/L; Metz + albumin, 500 μmol/L; Metz + albumin, 500 μmol/L + $CaCl_2$, 5 mmol/L.

Sulfhydryl content. Gel electrophoretic analysis of fibrinogen Metz, as well as electron micrographs of negatively contrasted Metz fibrinogen (not shown), revealed that Metz molecules were monomolecular and thus were not joined by intermolecular covalent (ie, disulfide) bridges. To investigate further whether the cysteine residues in fibrinogen Metz at position 16 were oxidized to disulfides, we evaluated the titratable sulfhydryl (SH) content using Ellman's reagent.[38] Normal fibrinogen, which has no free SH groups,[50] and Metz fibrinogen yielded <0.2 mol of titratable SH groups per mole of fibrinogen. We also used a more sensitive technique to detect the presence of SH groups by labeling with ^3H or ^{14}C iodoacetic acid. With this technique, the titratable SH content of Metz fibrinogen as well as that of normal peak 1 fibrinogen was 0.01 to 0.02 mol of SH/mol of fibrinogen.

DISCUSSION

Although many EM studies have been made of the structure of α-fibrin and $\alpha\beta$-fibrin, to our knowledge none have reported on the ultrastructure of β-fibrin. By using the critical point drying technique to process fibrin clots, we were able to preserve clot structure and obtain high-quality, detailed stereo images of β-fibrin and Metz β-fibrin and Metz β-fibrin clot networks. Our findings, coupled with turbidometric analyses, permitted a comparison of the structure of $\alpha\beta$-fibrin with that of β-fibrin and Metz β-fibrin.

It is clear from our present findings that release of FPB alone can give rise to clots whose features resemble those of α-fibrin in several important ways: (a) Both types of fibrin tend to form thick twisting cables displaying typical periodic cross-striations under physiologic buffer conditions. When polymerization takes place relatively slowly, both types of fibrin develop fine fibrillar network structures in addition to a relatively thicker cable network. The latter observation is consistent with previous studies indicating that fiber thickness is determined in part by the kinetics of fiber growth.[11,12,18-20] (b) The fibrils from both types of fibrin show the characteristic twisting described by Müller and colleagues[14] for fine clots. Regions containing fine fibrillar matrix structures, whether derived from normal (β-fibrin or $\alpha\beta$-fibrin) or Metz β-fibrin, are not easily distinguishable from the fine matrix formed by $\alpha\beta$-fibrin at high ionic strength/pH[14] or in a slowly polymerizing system under physiologic conditions (this study).

Twisting is not only a characteristic of native fibrin fibrils (ref. 14 and this study), but is also a prominent feature of microcrystals and fibrin clots prepared from enzymatically modified fibrinogen.[51,52] We infer from those results and from our present observations that fiber twisting is an inherent feature of fibrin assembly when polymerization is initiated by release of either FPA or FPB.

Slowly polymerizing αβ-fibrin or β-fibrin networks contain fine fibrillar substructures that are superimposed on and merge with thick, loosely packed fiber bundle networks. Such structures evidently reflect an intermediate phase of fibrin assembly during which thick cables coalesce from a fine fibrillar matrix to form the mature anastomosing cable network. This observation is consistent with the observations that under physiologic conditions mature fibrin assembly develops over a relatively long time[23] from protofibrils that subsequently undergo lateral aggregation to form thick fiber bundles.[10-12] The precise mechanism by which this assembly process takes place is not yet known.

Clot turbidity is reportedly a function of the second power of fiber diameter.[15,17,53] Therefore, such measurements are sensitive to the presence of thick fiber bundles but not to fine fiber networks. The widest cable structures we observed occurred in the coarse β-fibrin monomer clots, yet these gels ultimately developed lower turbidity than did the rapidly polymerizing coarse αβ-fibrin matrix or any other β-fibrin or αβ-fibrin network having lower mean fiber widths (Table 1). This seemingly paradoxical phenomenon may indicate that light scattering per se is not strictly a function of fiber width but may also be related to factors such as tightness of fiber packing, branching, etc. Further studies combining electron microscopy with detailed physical and rheological measurements of clot properties should be most useful in clarifying this issue.

In contrast to turbidity, measurement of clot permeability is a reflection of pore size, coarse clots having greater permeability than fine clots.[15,17-20] Shah and colleagues[17,18] observed that the permeability of fibrin formed at a low thrombin concentration did not rise in proportion to the increase in fiber thickness calculated from turbidity measurements. Such observations are consistent with our present demonstration that slow polymerization (αβ-fibrin or β-fibrin) is accompanied not only by increased fiber thickness, but also by the formation of fine fiber networks. Deductions on clot matrix structure based on turbidity and permeability measurements depend on the assumption of a uniform population of network fibers. This is evidently not the case (ref. 17 and this study), especially under circumstances that are intermediate to the extremes of fine and coarse fiber network formation.

Release of FPA and FPB exposes independent binding sites in the NH_2-terminal region of the molecule which appear to function cooperatively in the aggregation process.[28,29] Release of FPA exposes the "A" site, which becomes aligned with the complementary "a" site in the D domain of another molecule.[5,21] Similarly, FPB release evidently exposes a "B" polymerization site,[28,29] efficient utilization of which by the complementary "b" site may depend on proper alignment of two D domains in an αβ-fibrin polymer.[21] Substitution of cysteine for arginine at Aα 16 in fibrinogen Metz evidently impairs this process because Metz β-fibrin, unlike normal β-fibrin, has only a weak tendency for lateral aggregation. This impairment may be due to the existence of a disulfide bridge at Aα 16.[54] The substitution may impose conformational or steric changes that interfere with proper occupancy or orientation of the polymerization site unmasked by release of FPB, thus impairing optimal alignment of fibrils into bundles. Further study of this impairment may lead to new insights into the exact location of the region involved in the ability of fibrin to form lateral associations with other fibrin molecules.

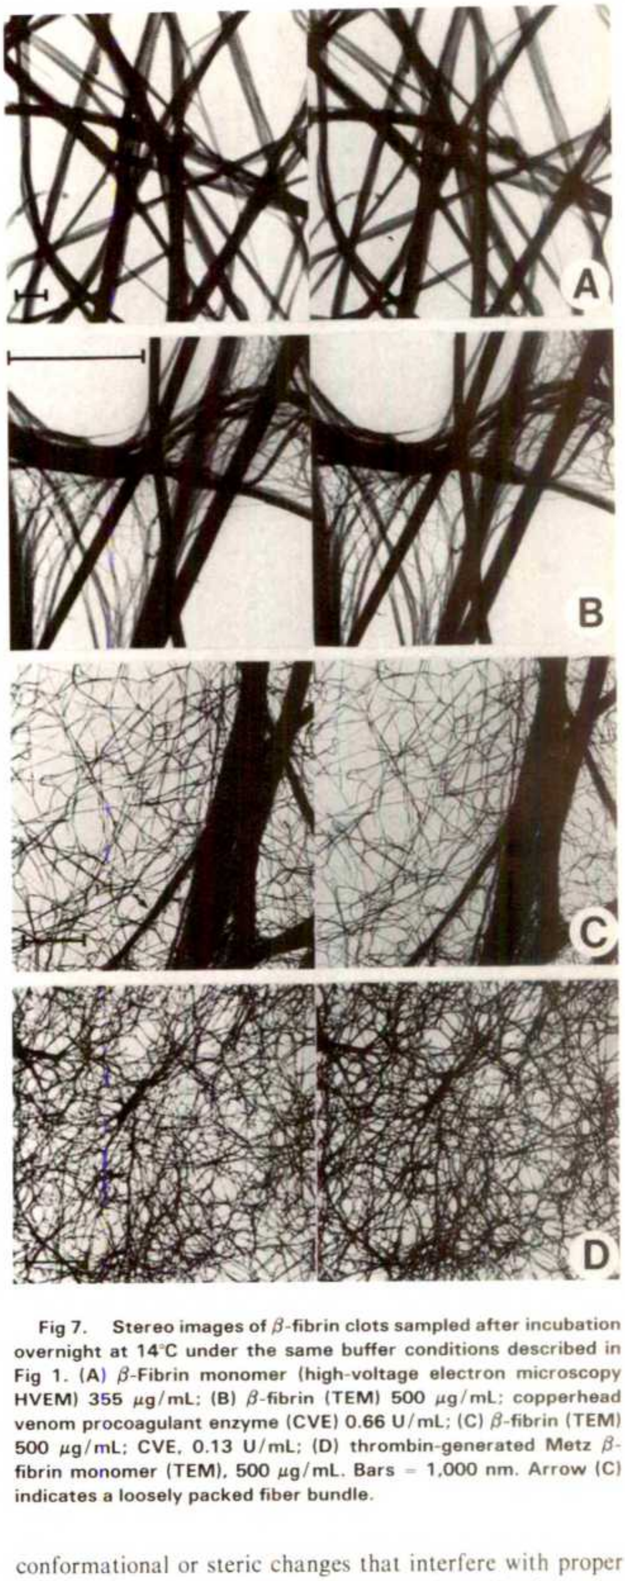

Fig 7. Stereo images of β-fibrin clots sampled after incubation overnight at 14°C under the same buffer conditions described in Fig 1. (A) β-Fibrin monomer (high-voltage electron microscopy HVEM) 355 μg/mL; (B) β-fibrin (TEM) 500 μg/mL; copperhead venom procoagulant enzyme (CVE) 0.66 U/mL; (C) β-fibrin (TEM) 500 μg/mL; CVE, 0.13 U/mL; (D) thrombin-generated Metz β-fibrin monomer (TEM), 500 μg/mL. Bars = 1,000 nm. Arrow (C) indicates a loosely packed fiber bundle.

In contrast to purified Metz fibrin, the Metz plasma clot was less fragile, could be synerized, and showed a considerable degree of lateral aggregation, even to the extent of forming easily discernible periodic striations (Fig 7). This "improvement" in Metz clot structure is not surprising since fibrin aggregation in plasma is associated with increased clot turbidity and increased lateral fiber aggregation.[47] When Metz fibrin was formed at concentrations approaching that in plasma or at an albumin concentration in the physiologic range (500 μmol/L), we were able to induce an increased degree of lateral fiber association. This effect was even more pronounced when Ca^{2+} was also present. We believe that the differences between purified Metz β-fibrin and plasma Metz β-fibrin structure are largely attributable to the fact that the plasma environment favors lateral fiber growth, due in part to the relative concentration of fibrinogen and to albumin or IgG.[46,47] Other plasma factors contributing to the strength and structure of the Metz plasma clot (eg, crosslinking) remain to be explored. In this regard, the Metz subject is not a severe or spontaneous bleeder, although she often bleeds for prolonged periods from venipuncture sites and is a habitual aborter.[30] Perhaps the relatively mild clinical bleeding that she manifests reflects the effect that the plasma environment has in enhancing fibrin clot formation.

Early T Cell Differentiated Chronic Myeloid Leukemia Blast Crisis With Rearrangement of the Breakpoint Cluster Region but Not of the T Cell Receptor β Chain Genes

By M. Gramatzki, C.R. Bartram, D. Müller, M. Walter, H. Tittelbach, and J.R. Kalden

Early T cell differentiation is described in a case of Philadelphia chromosome-positive chronic myeloid leukemia (CML) in blast crisis, supporting multi-lineage differentiation potential of CML precursor cells. In the absence of myeloid markers, strong positivity for terminal deoxynucleotidyl transferase (TdT) and reactivity with T cell antibody 3A1, but lack of more mature T cell antigens, provided evidence for immature T cell differentiation. Molecular analysis of the breakpoint cluster region (*bcr*) in chromosome 22 revealed a rearrangement and thus confirmed the CML origin of the early T cell blasts. T cell receptor β chain sequences were found in germline configuration and therefore suggest a very immature stage of T cell differentiation in the CML blasts.

CHRONIC MYELOID leukemia (CML) is believed to originate from a malignant transformation of a hematopoetic precursor cell, differentiated closely to the stem cell.[1] Although the common differentiation pathway of CML cells is myeloid, the occurrence of early lymphoid cells in certain cases of CML blast crisis,[2-4] isoenzyme studies,[5] the establishment of Philadelphia chromosome-positive mature B cell lines from CML patients,[6,7] and maturation studies of CML cell lines[8] suggest a multi-lineage differentiation potential of the malignant cell. Although approximately one-third of CML in blast crisis are lymphoid differentiated, T cell involvement has been distinctively rare and quite often disputed. Particularly in cases identified initially in blast crisis it may be difficult to assign the proper classification and to distinguish those from the Philadelphia chromosome-positive acute lymphoblastic leukemias (ALL).

More sophisticated cell surface marker analysis and gene rearrangement studies have recently become available. The use of such techniques in addition to characterization with conventional methods was applied to cells from a patient with CML blast crisis, and the diagnosis of early T cell CML could be established. Cytogenetical studies confirmed the diagnosis of CML by typical Philadelphia translocation[9] with rearrangement of the breakpoint cluster region (*bcr*).

Studies of the T cell receptor (TCR) β gene[10] revealed that these early T cell blasts had not yet been rearranged for the TCR. This report, for the first time, describes immunocytologically and genetically confirmed CML of early T cell differentiation lacking TCR β chain gene rearrangement.

MATERIAL AND METHODS

Immunocytological analysis. Peripheral blood mononuclear cells (PBMCs) were obtained by Ficoll-Metrizoate density-gradient centrifugation, and staining procedures were used as previously described.[11] Monoclonal antibodies used included OKT3, OKT4, and OKI-1[12,13] (Ortho Pharmaceuticals, Raritan, NJ); Leu-2[14] and Leu-M1[15] (Becton Dickinson, Mountainview, CA); B1 and B4[13,16] and My-7[13] (Coulter, Hialeah, FL); BA-1 and BA-2[17] (Hybritech, San Diego); 24.1[18] kindly provided by Dr Hansen, Seattle; Mo-S39 and Mo-U28[19] a gift of Dr Burmester (Erlangen) and Dr Winchester (New York) and the anti-T cell reagent 3A1.[20] Antibodies TH69 and TC25 were raised in our laboratory.[21] Specificities are described in the Results section. The percentage of positive cells as well as antigen density were assayed in an indirect immunofluorescent test and evaluated by fluorescence microscopy as well as fluorescent-activated cell sorter (FACS) analysis (EPICS V, Coulter) as previously described.[11,22] Irrelevant antibodies were used as negative controls, and an anti-HLA-class I antibody was used as positive control when appropriate. Cytocentrifuge-prepared cells were evaluated for presence of terminal deoxynucleotidyl transferase (TdT) according to a method of Bollum.[23]

Chromosomal analysis. Slides were prepared from 24-hour cultures made from a frozen stock of PBMCs. Conventional chromosomal analysis was performed using quinacrine fluorescence banding techniques for identification of chromosomes, and classification was made according to the Paris nomenclature.[24]

DNA analysis. DNAs were extracted from mononuclear cells after Ficoll-Hypopaque centrifugation by standard techniques. Fifteen micrograms of DNA was digested with appropriate restriction enzymes (Boehringer, Mannheim, FRG), electrophoresed on a 0.7% agarose gel, blotted and hybridized to 3′ and 5′ *bcr* sequences,[25] a

TCR β chain probe[26] and an Ig Cμ probe (kindly provided by Dr Leder). After hybridization, the filters were washed under stringent conditions and exposed to XAR-5 film (Kodak) using Dupont Lightning-Plus intensifying screens for 14 hours at −70°C.

Case report. A 53-year-old woman had a 6-month history of mild abdominal pain, weight loss, and low-grade fever. When she was admitted to the hospital, she had massive hepatosplenomegaly and, when examined hematologically had a WBC count of 113,000/μL. Anemia was mild, and her hemoglobin level was 9.8 g/dL. Thrombocytes were slighly elevated to 350,000/μL. Differential count revealed 79% blasts, 16% granulocytes, and 5% lymphocytes. The bone marrow aspirate demonstrated 90% blast cells of medium to large size with irregular, lobulated nuclear shape.

RESULTS

The patient's blast cells could not be classified into lymphoid or myeloid lineage by morphology alone (Fig 1). Cytochemical analysis of the blast cells revealed no reactivity in esterase, peroxidase, and periodic-acid Schiff (PAS) stains. TdT positivity, however, could be demonstrated in the indirect immunofluorescent test. Results of immunological analysis using a battery of monoclonal antibodies are shown in Table 1. Strong reactivity occurred with 3A1 (Fig 2), an antibody reacting with most mature and all immature T cells.[20] Blast cells reacted also with another anti-T cell antibody, designated TH69, which has specificity similar to that of 3A1 (ref. 21 and Gramatzki, unpublished observations). Early T cell differentiation was further suggested by absence of staining with the more mature anti-T cell antibodies[12,14] such as OKT3, OKT4, or Leu-2. Most cells expressed an antigen, detected by TC25, that is expressed only on some early T cell ALL, myelomonocytic and monocytic leukemias, and CML in blast crisis.[21] In contrast, <15% of the PBMCs of the patient had myeloid or monocytic antigens on their surface, as determined by antibodies Mo-S39, Leu-M1, Mo-U28, and My-7. Likewise, no evidence for B cell or immature non-T cell lymphoid differentiation was found using reagents B1, B4, BA-1, BA-2, and the anti-common ALL (CALLA) antibody 24.1. Ia-antigens were not detected, a familiar finding on malignant cells differentiated on the early T cell level.

Cytogenetic analysis revealed the presence of a Philadelphia chromosome (Fig 3). To study the Philadelphia translocation molecularly, configuration of the *bcr* gene residing on

chromosome 22 was analyzed. Southern blot analysis revealed a rearrangement within *bcr* (Fig 4).

Because the blasts were typed as early T cell origin, whether the gene for the T cell receptor β chain was already rearranged was of interest. Southern blot analysis, however, showed germline configuration (Fig 5).

To exclude any pre-B cell differentiation on the molecular level, Cμ sequences were used to investigate immunoglobulin heavy chain genes. Not surprisingly, they were found in germline configuration (Fig 6).

DISCUSSION

Because T cell differentiation of blasts in CML is a rare event,[7,13] it appears important to review the evidence for classification in this case. Absence of esterase and peroxidase staining, and lack of reactivity with several antibodies detecting different myeloid antigens, but presence of TdT, an enzyme marker associated with lymphoid differentiation,[4,27] was highly suggestive of a lymphoid affiliation of the patient's leukemic cells. Reactivity with T cell antibody 3A1, dissecting immature T cells from pre-B cell forms,[17,20,22] and lack of staining with antibodies defining Ia antigens, B cells, or mature T cells, finally established differentiation on the early T cell level. This was confirmed by demonstration of immunoglobulin genes in germline configuration.

Although the clinical situation with massive spleen enlargement and thrombocytosis was already suggestive of CML in blast crisis,[28,29] Philadelphia chromosome positive ALL,[24,30-32] although almost always of non-T non-B cell type,[24] had to be excluded. Recently, molecular techniques have become available which appear to be helpful in this situation.[9,28,32] The typical Philadelphia translocation seen in CML patients places the *c-abl* oncogene adjacent to *5′bcr* sequences on chromosome 22q −, whereas *3′bcr* sequences are translocated to chromosome 9q +.[33] Because true Ph^1-

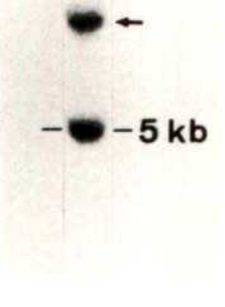

Fig 4. Southern blot analysis of *bcr* sequences; 15 μg of DNA obtained from peripheral blood cells and digested with BglII. Hybridization to a 5′ *bcr* probe detects a rearranged fragment (arrow) beside a 5-kilobase (kb) germline band.

positive ALL studied so far appeared to be different on the molecular level,[9,28,33-35] the typical *c-abl/bcr* rearrangement seen in our patient firmly establishes this T cell malignancy as a blast crisis of CML.

Recently, additional insight in T cell malignancies was obtained by studying the gene for the TCR,[10,36] and most but not all T cell tumors had the receptor genes clonally rearranged.[36-38] In this case of T cell CML, however, the TCR β gene was in germline configuration, which is in agreement with the immature differentiation level, since the receptor becomes rearranged during T cell maturation.[10] Very recently, two cases of T cell CML with already rearranged TCR were reported, in one of which typical *c-abl/bcr* rearrangement was documented as well.[39,40] The present study is the first report of a T cell CML blast crisis with TCR still in germline configuration, indicating heterogeneity of differentiation stages in T cell CML. This is supported by the few published cases of immunologically characterized T cell CML in which some were immature as well[41,42] and one apparently was late thymic-differentiated,[43] while Griffin and co-workers[13] reported a T cell CML with a mature phenotype that coexpressed myeloid antigens.

Our data provide definite evidence for the multilineage differentiation capacity for the CML precursor cell including the T cell lineage. Although T cell CMLs—despite their rarity—phenotypically are heterogeneous, they have certain molecular genetically defined alterations in common, namely a particular rearranged *c-abl/bcr* region. In turn, although *c-abl/bcr* rearrangement appears to define CML cells, immunological techniques and additional probes for other genetic sequences such as the TCR or the immunoglobulin genes are required for detailed evaluation of the differentiation stage of CML blasts.

ACKNOWLEDGMENT

Mediastinal Lymphoma of Clear Cell Type is a Tumor Corresponding to Terminal Steps of B Cell Differentiation

By Peter Möller, Gerhard Moldenhauer, Frank Momburg, Birgit Lämmler,
Maria Eberlein-Gonska, Sophie Kiesel, and Bernd Dörken

This article reports eight primary mediastinal tumors occurring in young adults (19 to 43 years, mean 29.4 years), predominantly female (six of eight) adults. Most patients responded badly to aggressive therapy. Progression is presently noted in one patient; five patients died 10, 11, 13, 18, and 22 months after diagnosis. No patient developed leukemia. The tumors were highly proliferative, had a diffuse growth pattern, and comprised clear cells of variable size. They could not be classified histologically, but could, however, be immunohistologically characterized as B cell lymphomas. In all cases, the immunophenotype was LC$^+$, cALLa$^-$, CD19$^+$, CD20$^+$, CD21$^-$, Ig (surface/cytoplasm)$^-$, and PC-1$^+$. In addition, the neoplastic cells exhibited variable defects in the expression of HLA-A,B,C and HLA-DR and inconstant expression of other B cell-restricted/associated antigens. This combination of immunophenotypical and clinical features suggests that the mediastinal clear cell lymphoma (MCCL) is a previously undescribed type of B cell lymphoma corresponding to the terminal steps of B cell differentiation.

© *1987 by Grune & Stratton, Inc.*

NORMAL PERIPHERAL B cells express major histocompatibility (MHC) antigens of class I (HLA-A,B,C) and class II (HLA-D), lineage-restricted differentiation antigens CD19, CD20, CD22 (reviewed by Nadler[1]) and carry immunoglobulin (Ig) on their surface. At the terminal stages of differentiation, the B cell differentiation antigens, HLA-D, and surface Ig disappear; plasma cell-associated antigens such as the PC-1, PCA-1,[2,3] and the T10 antigen[4] are expressed, and Ig is secreted in large amounts. In neoplastic B cells, however, deficient Ig expression may occur more frequently than initially assumed since most of the so-called "null"-cell lymphomas and common acute lymphoblastic leukemias are actually of B cell origin[5-10]; even chronic B lymphocytic leukemia is reported to lack detectable Ig constituents in a small percentage of cases.[11] Apart from Ig deficiency, cytomorphology of B cell tumors may be so deviant from that of B cells in physiologic development that they occasionally mimic T cell lymphomas,[12-15] Hodgkin's disease,[16] and even carcinoma.[17] The mediastinum is known to be the primary site of lymphoblastic T cell tumors ("T cell, convoluted" according to Lukes and Collins[18]), Hodgkin's disease,[19] and epithelial malignomas such as thymic carcinoma, and rarely of sarcoma (reviewed by Otto[20]). Even large series of malignant lymphomas, however, (eg, Brittinger and colleagues,[21] 1,127 cases; Tubbs and colleagues,[22] 564 cases), of mediastinal lymphomas (Bernard and colleagues,[23] 50 cases) and extranodal B cell lymphomas (Mohri,[24] 148 cases) fail to contain primary mediastinal tumors of proven B cell origin. Nevertheless, there are three reports on primary non-Hodgkin's lymphoma of the mediastinum[25-27] with pronounced aggressiveness and poor prognosis. Conspicuously, these lymphomas have a number of features in common: The patients were mostly young female adults presenting cough, chest pain, dyspnea, and venous obstruction as initial symptoms. The tumors apparently originating in the mediastinum tended to invade adjacent organs and structures and in most cases responded badly to antineoplastic treatment. As to morphology, the tumors were described as being of diffuse large cell type or as poorly differentiated, lymphocytic. In one series,[27] pronounced sclerosis was described as an additional characteristic feature. Concerning the immunophenotype, Perrone and colleagues[27] were able to prove the "lymphoreticular origin" of 53 of their 60 mediastinal tumors by applying a mixture of monoclonal antibodies to leukocyte common (LC) antigen on paraffin sections. Furthermore, immunoreactivity with antisera to κ and λ light chains suggested a B cell origin of five of these tumors. The remaining tumors described by the three groups of authors could be characterized, however, neither as B nor as T cell lymphomas using surface marker techniques available at the time of publication or by using formalin-fixed material.

Here we report that these mediastinal "null"-cell lymphomas are of B cell origin and present an immunophenotype that, although characterized by various defects, is indicative of a very late stage of B cell maturation.

MATERIALS AND METHODS

Patients. During the last 2 years, eight unusual primary mediastinal tumors were observed. They occurred in young (19 to 43 years, mean 29.4 years) predominantly female (6 of 8) adults. First clinical symptoms consisted of thoracic pain, thoracic venectasia, and dyspnea; B symptoms were noted in only 1 case. Tumor localization was described as mediastinal in 6 and as (para-)thymic in 2 cases. Initial diagnosis revealed involvement of the lungs in 3, of the pericardium in 2, and of cervical lymph nodes in 1 case; venous compression or invasion was observed in 3 patients. None was initially leukemic or developed leukemia. Serum electrophoreses were normal. The clinical course was characterized by therapeutic failure. Even though aggressive protocols against high-grade malignant lymphomas were

Table 1. Clinical Data

Case No.	Patient	Sex	Age at Diagnosis (years)	First Clinical Symptoms	Primary Localization	Tumor Cell Morphology	Preliminary Diagnosis*	Clinical Course After Surgical Intervention, Radiation and Chemotherapy
1	B.M.	F	19	Left breast venectasies; facial edema	(Para-) thymic	Large, polymorphic	Hodgkin's disease	Progression; liver infiltrations and abdominal lymphomas; tracheo-esophageal fistula; pneumonia; death 22 months after diagnosis
2	F.M.	F	21	B-symptoms: fever, night sweats, weight loss	Mediastinum	Large, polymorphic	Malignant lymphoma	Local progression; death 10 months after diagnosis with lung involvement and pericardic effusion
3	W.I.	F	31	Thoracic pain (left); dry cough	Mediastinum	Large and medium-sized, polymorphic	Malignant lymphoma	Local progression; death due to respiratory insufficiency 11 months after diagnosis
4	L.I.	F	35	Painful right shoulder/thorax; moderate dyspnea on exertion	Mediastinum	Relatively small, monomorphic	Malignant lymphoma	Local progression; abdominal lymph node involvement
5	G.S.	F	35	Thoracic pain, dry cough, moderate dyspnea on exertion	Mediastinum	Medium-sized to relatively small, monomorphic	Thymoma	Local progression; lung involvement; retroperitoneal lymphomas; death due to respiratory insufficiency 12 months after diagnosis
6	S.S.	F	43	Thoracic venectasies with cervical intumescence	Mediastinum	Medium-sized, monomorphic	Malignant lymphoma	Local progression; death due to respiratory insufficiency 18 months after diagnosis
7	K.M.	M	22	Mediastinal enlargement found in a routine X-ray	Mediastinum	Medium-sized, polymorphic	Hodgkin's disease	Presently in complete remission after combination chemotherapy
8	S.G.	M	29	Cervical swelling; facial and brachial edema	(Para-) thymic	Medium-sized, monomorphic	Malignant lymphoma	Progression; liver, kidney, and adrenal gland infiltrations; cervical lymphomas

*Done on the basis of routine hematoxylin and eosin sections for rapid notification.

applied in 7 cases, remission was achieved in only 1 case (patient 7, who received combination chemotherapy comprising endoxan, holoxan, vincristine, and prednisone [CHOP]). Five patients died 10, 11, 13, 18 and 22 months after initial diagnosis of extensive disease and large thoracic tumor masses causing respiratory insufficiency (Table 1).

Tumor tissue. Fresh tissue was transferred to our laboratory immediately after surgical removal. Representative samples were quick-frozen in liquid nitrogen. Frozen sections (4 to 6 μm) were air-dried overnight, fixed in acetone for 10 minutes at room temperature, and immunostained immediately or stored at −20°C for 1 to 3 weeks. Another sample was fixed in Bouin's fixative for routine processing purposes; histochemical stains from the paraffin-embedded material were achieved by using hematoxylin and eosin (H & E), periodic-acid Schiff's (PAS), Giemsa, and the Gomöri reticulin method; immunostaining of paraffin sections was preceded by bleaching and destruction of endogenous peroxidase by methanol/H_2O_2.

Reagents. Monoclonal antibodies (MAbs) to IgM (R1/69) and IgD (IgD26), to the leukocyte common antigen (2B11 and PD7/26), and anti–Ki-1 were obtained from Dakopatts, Copenhagen. MAbs against the T4 antigen (anti–Leu-3a (SK2)), the T8 antigen (anti–Leu-2b (SK3)), κ (163-42) and λ (1-155-2) light chains, to the interleukin-2 (IL2) receptor (2A3) and the CD22 antibody anti–Leu-14 were purchased from Becton Dickinson, Mountain View, CA. MAbs to the T11, T6, and T3 antigens were obtained from New England Nuclear, Seattle (Lyt3) and Ortho Diagnostics, Raritan, NJ (OKT6, OKT3), respectively. MAbs to common-ALL antigen (cALLa) (J5), to the B cell antigens CD20 (B1), CD21 (B2), CD19 (B4), and mAbs PC-1 and PCA-1, both directed against plasma cell-associated antigens, were furnished by Coulter Immunology, Hialeah, FL. MAbs specific to framework determinants of HLA-A,B,C (W6/32) and HLA-DR (2.06), and Blast-2, reacting with a B cell activation antigen (CD23 antigen) were generous gifts from the producing laboratories (given in references in Table 2); the B cell reagents HD6, HD28, HD37, HD237, HD39, and HD50 are products of some of us (B.D., G.M., S.K.), as is the antibody HEA125 that reacts with a surface glycoprotein (Egp34) restricted to normal and neoplastic epithelial cells (G.M., F.M.).

A polyclonal biotinylated sheep antibody to mouse Ig and a streptavidin-biotinylated peroxidase complex, both obtained from Amersham Buchler, Braunschweig, FRG, served as detection system for the monoclonal primary antibodies. Unconjugated rabbit-derived antisera to human μ-, γ-, α-, ϵ-, κ-, and λ-chains, swine anti-rabbit Ig serum and peroxidase–rabbit antiperoxidase complex were purchased from Dakopatts. Anti-human δ-chain and J-chain sera were obtained from Nordic Immunology, Tilburg, Netherlands. Pooled human IgG (Gamma-Venin) was supplied by Behringwerke, Frankfurt, FRG, 3-amino-9-ethyl carbazole (AEC) and *N'N*-dimethylformamide (DMF) were obtained from Sigma, St Louis.

Staining procedures. MAbs in culture supernatants were used undiluted; ascites preparations were used as 1:200 dilutions. The anti-mouse Ig antibody was diluted 1:50, and the streptavidin–peroxidase complex was diluted 1:100. Dilutions of primary antisera ranged from 1:50 to 1:1500; the anti-rabbit Ig antiserum was diluted 1:20, and the peroxidase–antiperoxidase complex was diluted 1:100. All dilutions and washing steps were carried out in phosphate-buffered saline (PBS); the secondary antibody solution contained 5% pooled human IgG to inhibit cross-reactions with human surface Ig. Incubation times of tissues were 1 hour at room temperature for the primary antibody (respective antiserum) and 30 minutes for the second-step and third-step reagents. Using AEC as the chromogen (0.4 mg/mL in 0.1 mol/L of acetate buffer pH 5.0 with 5% DMF and 0.01% H_2O_2 for 10 minutes), the peroxidase reaction resulted in

MHC, major histocompatibility complex.

an intense red precipitate. The sections were counterstained with Harris' hematoxylin and mounted with glycerol gelatin.

Controls. To obtain reliable results, the detection of Ig components was performed twice, using antisera on paraffin sections and mAbs on frozen sections. Positive controls were made at the same time, using paraffin and frozen sections from tonsils to ensure that a negative result on the tumor tissue was reliable and not due to the method. Intrinsic positive controls for the immunoreactivity of the MHC antibodies were interstitial dendritic cells, endothelial cells, and macrophages that, by their staining, indicated the reliability of the reaction and thus excluded false-negative results. Negative controls were performed by omitting the primary antibody (antiserum). No staining was observed, except for the reaction of intermingled granulocytes in frozen sections whose endogenous peroxidase was not destroyed.

RESULTS

Histomorphology. Most of the tumors showed a diffuse growth pattern (Fig 1). The cells had clear and abundant cytoplasm in common but varied considerably in size. The nuclei were roundish to very irregular; one tumor contained cells with multilobated nuclei, and a second revealed giant cells with extremely pleomorphic nuclei resembling Reed-Sternberg cells. The nucleoli were predominantly small and mostly singular. In cases 1 and 2, the tumor cells are best described as large and pleomorphic; in case 3 as mixed, large and medium-sized and pleomorphic; in cases 6 and 8 as medium-sized monomorphic; and in case 5 (Fig 1) as mixed, medium-sized to relatively small but monomorphic. The smallest tumor cells, however, were twice as large as the diffusely infiltrating normal lymphocytes that were a regular constituent of the lesion. Tumor necroses, mostly ill-defined and small but never confluent, were observed in six cases. Mitoses were numerous and always typical. Even more frequent were single-cell degenerations. The tumors were further characterized by an alveolar to microalveolar reticulin fiber scaffold; case 1 showed pronounced sclerosis. In conclusion, the histologic picture of these tumors was not compatible with any of the morphologically defined B cell lymphomas listed in the current classifications. The histomorphology of these lymphomas resembles either pleomorphic peripheral T cell lymphoma or thymoma; in two cases, it even resembled Hodgkin's disease.

Immunophenotype. (Table 3) The tumors were LC$^+$ and HEA125$^-$ and thus clearly defined as nonepithelial in nature. They all expressed the B cell-restricted antigens CD19 and CD20, as could be shown by the binding of mAbs HD37, HD237, B4, and B1, respectively. The first three mAbs showed minor differences in binding intensity in five cases; B4 failed to react with tumors 3 and 7. CD22 was expressed on the tumor cells of six cases but was undetectable

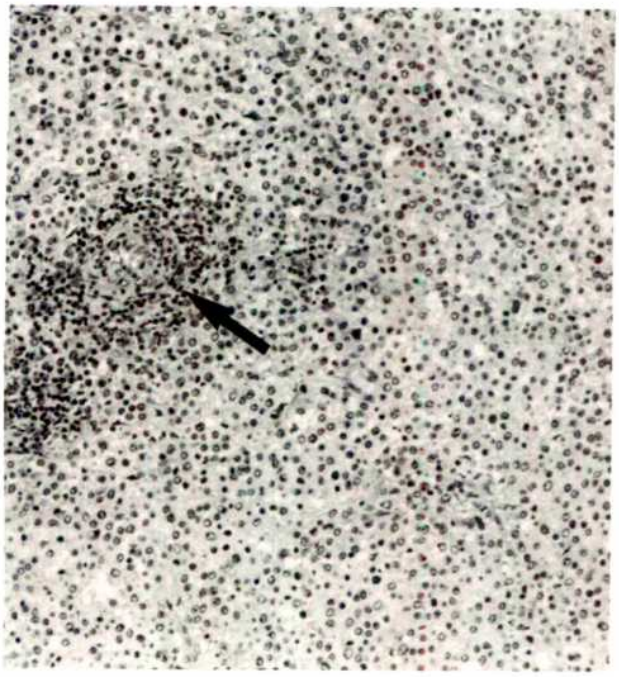

Fig 1. Primary mediastinal clear cell lymphoma of B cell type: Case 5. Predominantly medium-sized tumor cells with very pale cytoplasm and roundish nuclei, diffuse growth pattern. Arrow: vessel surrounded by normal peripheral (T) lymphocytes. Hematoxylin and eosin; original magnification ×140.

in cases 3 and 8. CD23, a putative B cell activation antigen, was present on tumor cells of cases 1 and 4 (Fig 2) and on a minor part of the neoplastic cells of cases 7 and 8. Two other activation antigens, Ki-1 and the IL 2 receptor, could not be detected. Immunoglobulin constituents (heavy and light chains, J chain) were not detectable in the whole tumor series in either the cytoplasm or on the surface of the tumor cells. Ig of various light and heavy chain classes was present only in mature, morphologically typical plasma cells, which, however, were very scarce. In addition, one case contained minute islands of small, round lymphoid cells carrying surface IgM (Fig 3). The neoplastic cells of every case strongly bound PC-1, a mAb recognizing a plasma cell-associated antigen (Fig 4). PCA-1, another mAb of this category, reacted in cases 5 and 6 with the entire neoplastic population and in a varying number of tumor cells of cases 1, 2, and 4. MAb OKT10, also known to bind to normal plasma cells, reacted with tumor 2 and with parts of the neoplastic population of case 4 CALLA and CD21 could not be detected in either case. The tumors showed variable deficiencies in MHC antigen expression: at least two cases completely lacked class I and class II antigens (Fig 5); a third case (case 6) contained only a very small number of scattered HLA-ABC$^+$ and HLA-DR$^+$ large cells among the unreactive tumor cells (Fig 6); although probably of histiocytic origin, it cannot be completely ruled out that those cells were part of the neoplastic population. Four other tumors contained varying proportions of MHC antigen-deficient neoplastic cells. The coordinate expression of class I and class II

•−, Negative; +, positive reaction on the entire tumor cell population; (+), weakly positive; ±, positive and negative tumor cells in equal parts, +, negative tumor cells clearly outnumber positive ones; − ≫ +, very few scattered positive cells, putative tumor cells.

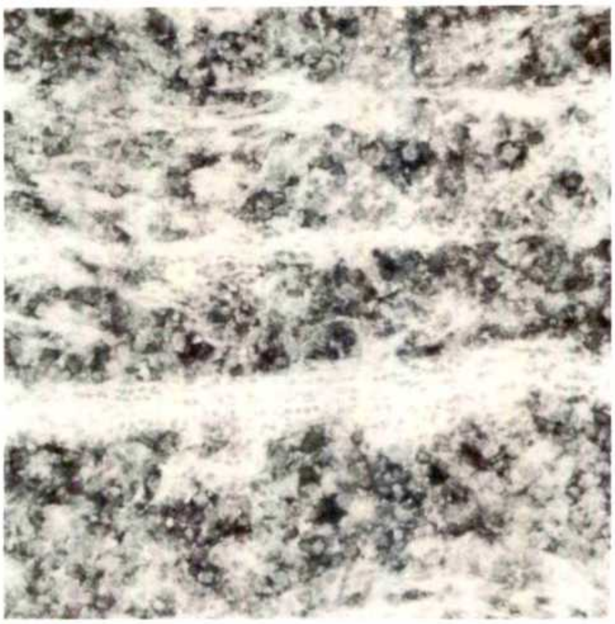

Fig 2. Case 4. Monoclonal antibody (MAb) HD50 recognizing the activation-associated CD23 antigen bound in varying intensity to the tumor cell population but not to the stromal cell component of the lymphoma. Immunoperoxidase; original magnification ×122.

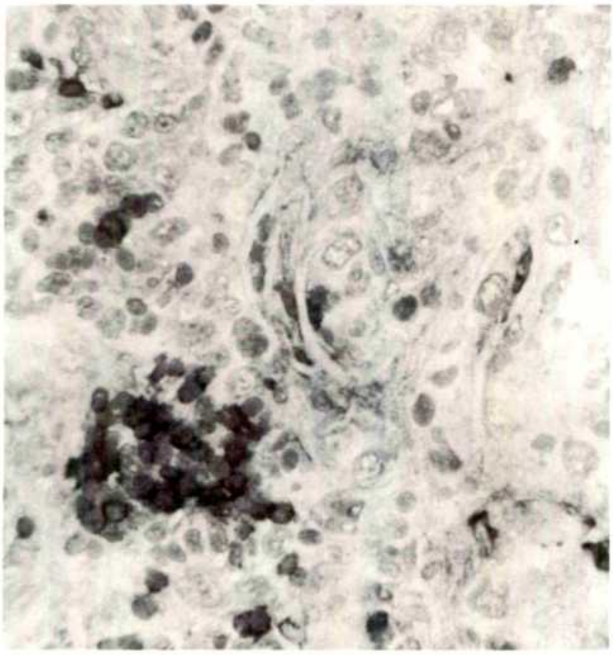

Fig 3. Case 2. Demonstration of IgM by monoclonal antibody (MAb) R1/69. The large tumor cells were devoid of detectable IgM whereas scattered reactive small lymphocytes stained strongly, thus excluding a false-negative result. Immunoperoxidase; original magnification ×305.

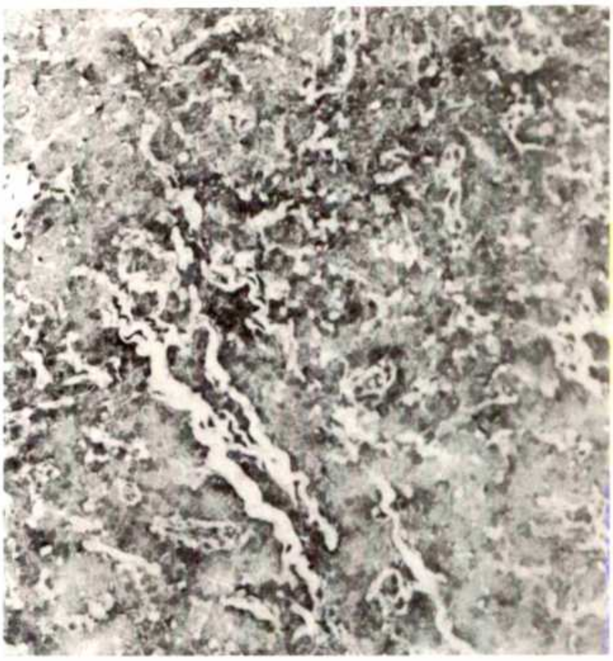

Fig 4. Case 8. Monclonal antibody (MAb) PC-1 recognizing a plasma cell-associated antigen bound strongly to the entire tumor cell population. Negative connective tissue fibers are apparent. Immunoperoxidase; original magnification ×133.

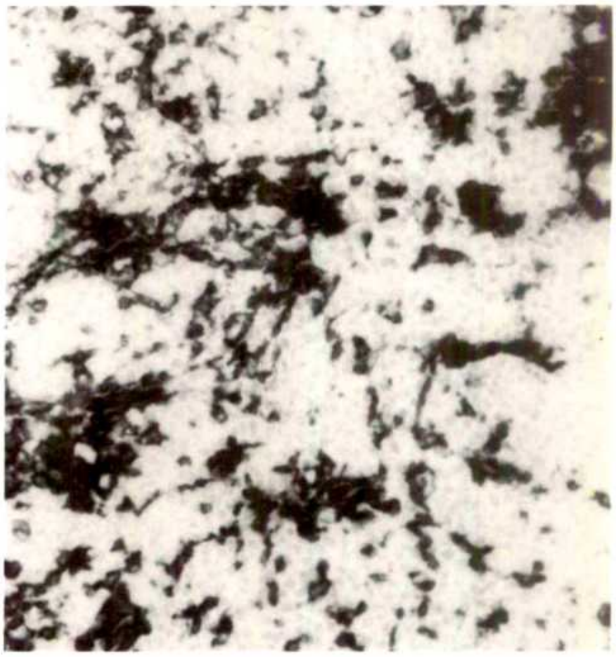

Fig 5. Case 5. Monoclonal antibody (MAb) W6/32 strongly stained dendritic interstitial cells and small infiltrating lymphocytes but did not bind to the tumor cell population, thus indicating its abnormal loss of HLA-A,B,C molecules. Immunoperoxidase; original magnification ×122.

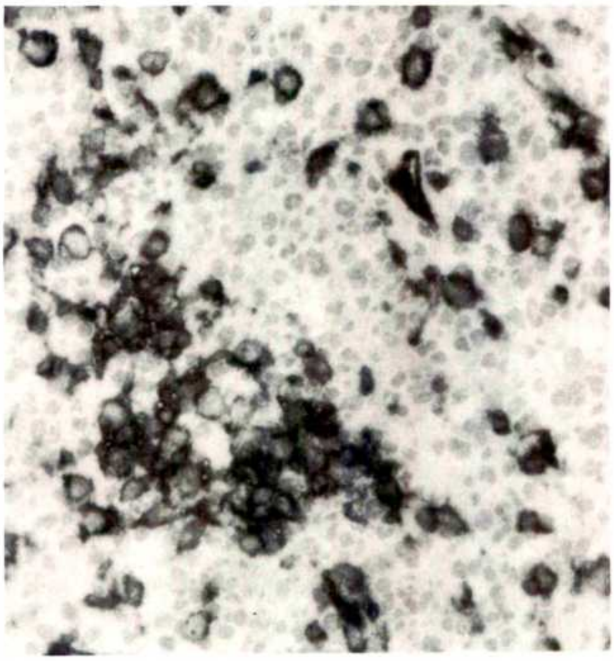

Fig 6. Case 6. Monoclonal antibody (MAb) 2.06 recognizing a HLA-DR framework determinant failed to react with the tumor cells but stained interstitial dendritic cells and a small proportion of large scattered cells, most probably of histiocytic origin. Immunoperoxidase; original magnification ×195.

antigens was noticed only in case 2. MAbs directed against T cell antigens T6, T11, T3, T4, and T8 exclusively stained small lymphoid cells interspersed in various amounts with the tumor cells and occasionally crowded around blood vessels (Fig 1). The epithelium-specific mAb HEA125 showed reactivity in neither case.

In sum, this series of eight polymorphic mediastinal tumors is characterized by variable defects in MHC antigen expression, by the constant phenotype $CD10^-$, $CD19^+$, $CD20^+$, $CD21^-$, $PC\text{-}1^+$ and complete Ig deficiency, suggesting that they represent tumors of terminal B lymphocyte differentiation.

DISCUSSION

In several aspects, the clinical features of our patients with primary non-Hodgkin's lymphoma of the mediastinum resemble those of the patients described by Levitt and colleagues,[25] Trump and Mann,[26] and Perrone and colleagues.[27] As compared with mediastinal T lymphoblastic lymphoma, which has pronounced male predominance (eg, Brittinger and colleagues,[21] ratio of males to females 9:1), there seems to be a clear female predominance for mediastinal "null"-cell lymphoma: 6 of 12 of the patients of Levitt and colleagues, 7 of 11 of the patients of Trump and Mann, 43 of 60 of the patients of Perrone and colleagues and 6 of 8 of those in our series were female. Nine of those of Levitt and colleagues, 8 of Trump and Mann's, and 7 of our patients were younger adults (19 to 37 years); 85% of Perrone and colleagues' group were aged ≤35 years. Cough, chest pain, dyspnea, and venous obstruction were common initial signs. Apart from mediastinal mass, there was additional tumor involvement of pericardium at initial examination in three of the patients of Levitt and colleagues, 1 of the patients of Trump and Mann, and in 2 of the patients of our series; lung involvement was noted twice in Levitt and colleagues' group, 3 times in Trump and Mann's group, and 3 times in our group of patients. The chest wall was the most frequent site of extrathoracic involvement in Perrone's series. When given aggressive antineoplastic treatment, 10 of the patients of Levitt and colleagues reached a transient complete remission, but neither of Trump and Mann's patients and only one of our patients was regarded as disease-free afterwards. No patient developed leukemia. Progressive disease, relapse, and chemotherapeutic failure was commonly noted. Four of the patients of Levitt and colleagues, 8 of Trump and Mann's, 20 of the patients of Perrone and colleagues, and 5 of our patients were dead at time of publication, with a survival time ranging from 4 to 22 months; median survival given by Trump and Mann was 16 months. To conclude, we feel that we are dealing with a lymphoma type with a rather distinct clinical picture.

Our central finding is that these tumors are B cell lymphomas. Referring to the B cell differentiation scheme given by Nadler,[1] the immunophenotype LC^+, $CD10^-$, $CD19^+$, $CD20^+$, $CD21^-$, ($Ki1^-$, T cell antigens$^-$), common to all the tumors of our series, suggests a terminal B cell differentiation. This view is supported by the presence of the plasma cell-associated antigens PC-1 in 8 of 8, PCA-1 in 5 of 8, and T10 in 2 of 8 tumors, indicating that at least a partial plasma cell phenotype is expressed although cytomorphology is never plasmocytic. On the basis of the PCA-1 reactivity of neoplastic cells, Anderson and co-workers[45] characterize hairy cell leukemia as a tumor of the pre-plasma cell. Plasmacytoma, plasma cell leukemia, and myeloma are reported to express PCA-1,[45] PC-1,[2] and (OK)T10.[46,47] On the other hand, the diffuse large cell lymphomas of B cell type analyzed by Freedmann and co-workers[48] failed to express PCA-1 and PC-1, a finding that caused them to argue that these tumors are the neoplastic counterparts of normal B cells at the midstage of differentiation. Based on these observations the immunophenotype of the aleukemic lymphomas described herein indicates that it is probably a novel B lymphoma type. It might be placed between tumors of midstage differentation and hairy cell leukemia/plasma cell tumors. This tumor cell variant might alternatively be regarded as the malignant counterpart of the final stage of an alternative pathway of B cell development: the monocytoid B cell, also known as the cell of the so-called "immature sinus histiocytosis,"[49-52] which is a B cell that cannot be located in the current physiological differentiation scheme. In this context, it is noteworthy that monocytoid B cells have clear cell morphology and are $PCA\text{-}1^+$ (P. Möller, unpublished observations).

Nevertheless, as compared with the normal mature B cell, the tumor cells of MCCL exhibit considerable lacks in antigen expression. There are no Ig constituents. This complete loss of Ig has been observed by several authors (discussed previously) to occur in large cell B lymphomas of unknown or follicular origin. Two of our tumors failed to express the CD22 antigen, as could be verified by staining with three different mAbs. This may be interpreted in two ways. CD22 expression may either have been impaired by a defect in gene expression or abrogated in the course of terminal differentiation. Furthermore, there are minor irregularities in the binding of CD19 mAbs: HD237 failed to react with a subset of neoplastic cells of case 3; B4 did not recognize tumors 3 and 7. Whether this is due to inaccessibility or defect of the corresponding epitope or just to a lesser affinity of these antibodies cannot be answered. Because the CD23 antigen seems to be closely related to activation,[39] the partial or complete nonexpression of the CD23 antigen in six of eight tumors is probably of functional nature. Severe defects, however, must be suspected because of the partial or complete nonexpression of MHC class I molecule (HLA-A,B,C) observed in all tumors but one. To our knowledge, very few reports exist describing lack of class I antigen expression in malignant lymphoma: Woda and co-workers[53] observed this lack in three cases of large "histiocytic" B cell lymphomas, and the Daudi cell line is known to be devoid of β_2-microglobulin,[54] which is part of the heterodimeric class I molecule. Because class I antigens serve as restriction elements of T cell-mediated cytotoxicity,[55] HLA-A,B,C-deficient tumor cells possibly escape immune attack by cytotoxic T cells.[56] This may account for the clinical aggressiveness of the primary mediastinal B cell lymphomas.

Six of eight of the tumors had either partial or complete defects in expression of the HLA-DR framework determinant recognized by mAb 2.06. Defects in class II antigen expression in B cell lymphomas were sporadically noted by several authors.[57-61] Our evaluation of the staining for HLA-DR probably underestimates the real extent of nonreactivity within the neoplastic population since intermingled small negative cells were regarded as reactive T cells, as was suggested by parallel sections stained with mAbs to T cell antigens. For multiple myeloma, it was assumed that the neoplastic plasma cells lost their class II antigens while entering the terminal stage of differentiation.[45-62] Although we discuss this stage of development for our tumor group, a down-regulation of MHC class II antigen expression seems more unlikely to us than assumption of a pathological loss, ie, a further defect in antigen expression since all tumors lacking class II molecules were also class I antigen-deficient. Class II antigens are transducers for B cell activation[63-65] and maturation.[66] Thus, a defective expression of these important trigger molecules might contribute to the incomplete differentiation of the neoplastic B cells in the primary mediastinal lymphoma of clear cell type.

ACKNOWLEDGMENT

We are indebted to Dr H. Schmitteckert from the LVA-Klinik für Thoraxkrankheiten (Heidelberg/Rohrbach) for supplying clinical data, to Ingeborg Brandt and John Moyers for technical assistance, and to Christine Raulfs and Hans-Ulrich Burkhardt for help in editing the manuscript.

G-150 for gel filtration. The C1̄-INH prepared by this method was usually a homogeneous single band in SDS analytic gel electrophoresis, but some preparations demonstrated two closely approximated bands.[8,9] Recoveries were as high as 70% of that in the starting plasma.

Plasma kallikrein was isolated according to the procedure of Nagase and Barrett,[10] which was modified to include a second step in affinity chromatography with SBTI-Sepharose following chromatography on Ultrogel AcA 54. In addition, immune adsorption on a column of Sepharose-antihuman IgG was used to remove contaminating immunoglobulins at the end of the purification. This kallikrein was homogeneous in SDS analytic gel electrophoresis when freshly prepared, or a doublet, and had a specific activity of approximately 176 units of coagulant activity per milligram of protein. In determining the specific activity of plasma kallikrein preparations, a coagulation assay was used[11] in which one unit of activity is defined arbitrarily as the amount in 1.0 mL of pooled normal human plasma. During storage at −30°C, autodigestion products formed of 67,000 and lower mol wt. Cleavage products of less than 52,000 mol wt, induced by cleavage by factor XIIa, have been shown to have reduced ratios of coagulation to amidolytic activity.[12]

C1s̄ was prepared by the method of Bing and his colleagues[13,14] and gave a homogeneous single band in SDS-analytic polyacrylamide gel electrophoresis when freshly prepared. This material had a specific activity of over 1,000 U/mg of protein.[1] Some degradation of the C1s̄ used has occurred in the present studies, providing lower mol wt bands visible in stained gels (see figures) after EDTA was removed during gel filtration.

SDS-polyacrylamide gel analyses were performed using a Hoefer Vertical Gel Electrophoresis system and was carried out either in 7.5% polyacrylamide, according to the method of Laemmli[15] or in gradient gels prepared using a modification of this method in which a gradient of 7.5% to 12.5% (wt/vol) acrylamide was prepared as reported previously.[8] Gel-bond (FMC, Marine Colloids Division, BioProducts, Rockland, ME) was inserted between the glass plates into which the gels were poured for vertical electrophoresis to stabilize the gels. After adding SDS, the mixtures were incubated at 37°C for another 30 minutes, instead of boiling, to avoid aggregation of proteins. Electrophoresis was carried out at 3 to 3.5 V/cm for 18 hours at room temperature or until the tracking dye was within 1 to 2 cm of the bottom of the gel when gradient polyacrylamide gel was used. When a single concentration of polyacrylamide gel was used, electrophoresis was carried out at 4°C until the tracking dye was near the bottom of the gel. After staining with 0.25% Coomassie brilliant blue, the gels were fixed in mixtures of 33% methanol, 15% trichloroacetic acid, and 3% sulfosalicylic acid for 30 minutes, followed by washing in an aqueous mixture of 5% acetic acid and 16% glycerol overnight.

RESULTS

Interactions of C1s̄ and plasma kallikrein with normal C1̄-INH. When purified normal C1̄-INH was incubated with plasma kallikrein for as short a period as five minutes at 37°C, stable complexes between kallikrein and the inhibitor formed (Fig 1). These complexes appear to involve the component of C1̄-INH of about 106,000 mol wt but not that of approximately 96,000 mol wt, even when the concentration of kallirein was in molar excess with respect to the inhibitor (Fig 1A). In experiments not shown, complexes between the *lower* mol wt component of C1̄-INH and kallikrein in equimolar amounts or in enzyme excess failed to

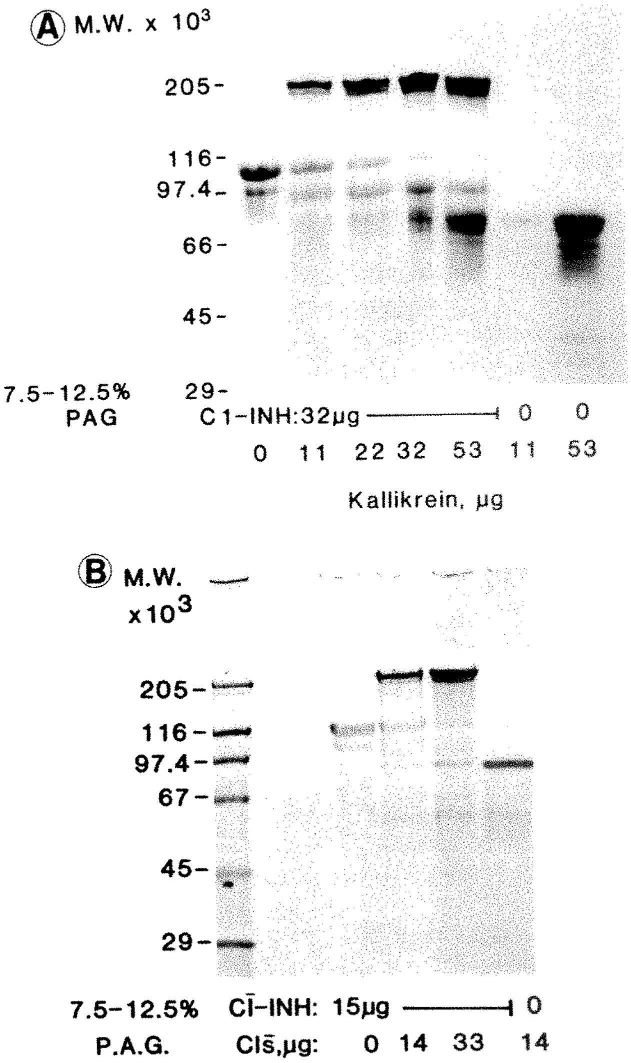

Fig 1. (A) Variable amounts of purified plasma kallikrein were incubated with 32 µg of purified normal C1̄-inhibitor at 37°C for 20 minutes. SDS was added, the mixtures incubated at 37°C for another 30 minutes, and were then subjected to electrophoresis in a vertical thin slab of polyacrylamide gel in graded concentrations of 7.5% to 12.5%. The sample in the left lane (not shown) was a mixture of proteins of known mol wt, noted to the left. The sample in the lane to the far right was plasma kallikrein alone (K), which was partially degraded. Note that the lower mol wt form of C1̄-INH was not consumed in complexes with kallikrein, even in enzyme excess (lanes 2 to 5) and that this band assumes a position of lower mol wt materials after exposure to kallikrein than in the "native" state (lane 1). (B) The same preparation of purified C1̄-INH was incubated with increasing amounts (left to right) of C1s̄ at 37°C for 20 minutes before SDS was added and incubation continued for an additional 30 minutes at 37°C. Samples were then subjected to electrophoresis in thin slab vertical gels consisting of graded concentrations of polyacrylamide from 7.5% (top) to 12.5% (bottom, anode) as above. The positions of bands of proteins of known mol wt are indicated at the left. Note that both the higher and lower mol wt components of C1̄-INH appear to participate in complex formation with C1s̄ (lanes 3 and 4). The lower mol wt component appears to have been cleaved by C1s̄ (lane 3); this cleavage was not visible in ungraded gels. The apparent mol wt of the individual proteins is higher in this gradient gel system than in a continuous concentration of polyacrylamide.

occur during incubation for as long as two hours. On the other hand, when C$1\bar{s}$ was incubated with this preparation of C$\bar{1}$-INH, both components of the C$\bar{1}$-INH appeared to become involved in complexes with C$1\bar{s}$ (Fig 1B). These observations suggest that there are different structural requirements for the formation of stable complexes between normal C$\bar{1}$-INH and kallikrein than with C$1\bar{s}$.

When a purified preparation of normal C$\bar{1}$-INH, which was apparently homogeneous having a mol wt of 106,000, was used, it was cleaved by both C$1\bar{s}$ and kallikrein during incubation for brief periods at 37°C (Fig 2). The cleavage product had an approximate mol wt of 96,000. A major high mol wt complex formed with each enzyme and this inhibitor. The mol wt of the complex with C$1\bar{s}$ was approximately 182,000 and that with kallikrein was 185,000 (Fig 2). The C$\bar{1}$-INH was not completely consumed in this experiment, probably because the C$1\bar{s}$ used had a lower specific activity than that used in the experiment shown in Fig 1B. In an experiment not shown here, a preparation of C$\bar{1}$-INH, which had lost most of its activity against C$1\bar{s}$, consisted of two lower mol wt components of approximately 95,000 and 92,000. Neither of these formed a complex with plasma kallikrein.

Interactions of plasma kallikrein with dysfunctional C$\bar{1}$-INH. Dysfunctional C$\bar{1}$-INH proteins from members of eight different kindred with type II HANE were purified and analyzed for their interactions with plasma kallikrein. The subjects from whom plasma was obtained were not receiving androgen therapy at the time, with the exception of one preparation from subject Da, noted below, and therefore did not have therapeutically induced increases in serum concentrations of normal C$\bar{1}$-INH. These proteins were examined for their interactions with C$1\bar{s}$ and plasmin in work reported earlier.[8] Table 1 summarizes the interactions of these proteins with kallikrein and compares them with their interactions with C$1\bar{s}$, most of which were reported in an earlier study.[8] In these studies the kallikrein and inhibitor proteins were incubated together at 37°C for 20 minutes before SDS was added, and electrophoresis was performed in SDS gels. The preparation of C$\bar{1}$-INH from subject Bo contained a single low mol wt contaminant, and C$\bar{1}$-INH from subject Ta contained a single unidentified high mol wt contaminant visible in SDS gel. The preparation of C$\bar{1}$-INH from Da, which formed a stable high mol wt complex with kallikrein, was obtained when this patient had received androgen therapy and probably contained detectable amounts of normal C$\bar{1}$-INH. It was not possible to distinguish the normal protein from some of the dysfunctional protein in these gels. Other preparations from this subject failed to form complexes stable in SDS gels.

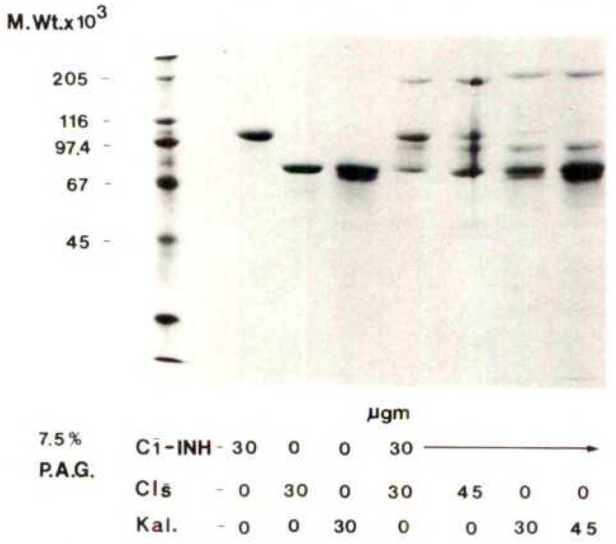

Fig 2. In this 7.5% polyacrylamide gel, the electrophoretic behavior of 30 µg of normal single band C$\bar{1}$-INH following incubation for 20 minutes with increasing amounts of C$1\bar{s}$ or kallikrein (µg), shown at the bottom, are compared. This C$\bar{1}$-INH was a preparation of high specific activity; the C$1\bar{s}$ was of lower specific activity than that used in Fig 1B. Mol wt standards are shown to the left and in lane 1; untreated C$\bar{1}$-INH alone is in lane 2, C$1\bar{s}$ alone in lane 3, and kallikrein alone in lane 4. The mixtures did not run at an identical rate in this gel (the running front was convex), but the calculated mol wt of the C$\bar{1}$-INH cleavage fragment generated by C$1\bar{s}$ was 96,000 and that generated by kallikrein was 94,000. Moreover, the C$\bar{1}$-INH-kallikrein complexes were of a higher mol wt (lanes 7 and 8) than the C$\bar{1}$-INH-C$1\bar{s}$ complexes (lanes 5 and 6).

In the experiment illustrated in Fig 3, kallikrein was incubated with the inhibitor proteins at 37°C, as above, and before electrophoresis SDS was added, and the mixtures were incubated at 37°C for 30 minutes, instead of boiling, to

Table 1. Interactions C$\bar{1}$-INH Proteins with C$1\bar{s}$ and Kallikrein

	Activity: % of Normal v		Complex Formation with		Cleavage by

The first column designates the abnormal C$\bar{1}$-INH from kindred with HANE by the first two letters of the kindred name, and the second and third columns provide the levels of inhibition of C$1\bar{s}$ and kallikrein by each dysfunctional C$\bar{1}$-INH as compared to that of the normal C$\bar{1}$-INH, which were published earlier.[8] The inhibition of C$1\bar{s}$ and kallikrein by normal C$\bar{1}$-INH were arbitrarily determined to be 100%. The percent of inhibition provided by each dysfunctional C$\bar{1}$-INH was calculated by dividing the reduction rate of hydrolysis of synthetic substrates by each enzyme, in nanomoles per minute per microgram of dysfunctional inhibitor, by the reduction in rate per minute per microgram of normal C$\bar{1}$-INH × 100. Each dysfunctional C$\bar{1}$-INH was tested four to six times against each enzyme using different quantities of inhibitor.[8] Kallikrein inhibition was measured with a synthetic chromogenic amide (S-2302, Kabi, Stockholm, Sweden) and inhibition of C$1\bar{s}$ by the method of Levy and Lepow,[1] which employs an acidometric titration of N-acetyl-L-tyrosine ethyl ester hydrolysis. The reduction in rate of esterolysis in the presence of the inhibitor proteins by a preparation of C$1\bar{s}$ in units per milligram of protein was calculated. Columns 4, 5, 6, and 7 indicate whether or not complex formation occurred between C$1\bar{s}$, kallikrein (+ = stable complexes) and each inhibitor and if the inhibitors were cleaved (+) by either enzyme.

*With molar excess of enzyme only (2:1).

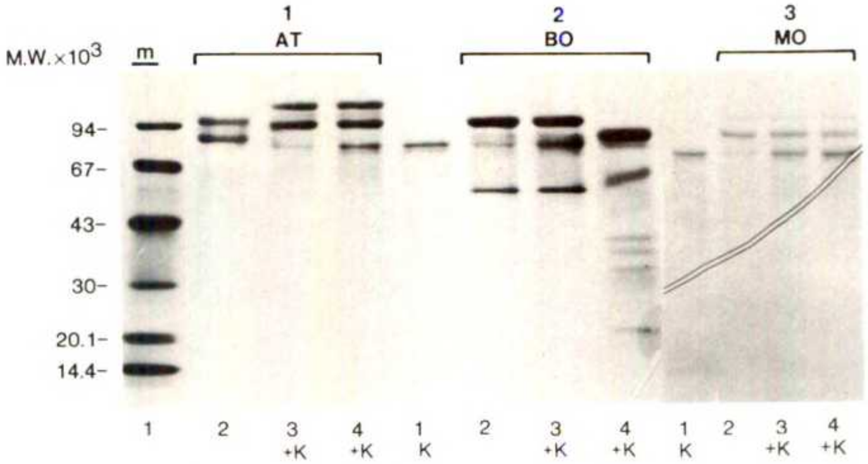

Fig 3. Each purified dysfunctional C$\bar{1}$-inhibitor protein is indicated by the first two letters of the kindred name, shown at the top of the gel, describing its electrophoretic behavior following preliminary incubation with one or more quantities of purified plasma kallikrein (K). Lane 1 (A) contained proteins (m) of known mol wt, indicated to the left. The gels contained concentrations of polyacrylamide graded continuously of from 7.5% at the top of the gel to 12.5% at the bottom (anode). The amounts of kallikrein and of C$\bar{1}$-INH proteins were: (A, B) C$\bar{1}$-INH At and Bo, 31 μg; kallikrein, 30 μg (lane 3) and 60 μg (lane 4); Lane 1, (B), kallikrein alone, 30 μg. (C): C$\bar{1}$-INH Mo, 28 μg (lanes 2 to 4); kallikrein, 30 μg (lane 3) and 60 μg (lanes 1 and 4). Although a somewhat higher mol wt band was generated in mixtures of C1-INH At and kallikrein, low mol wt fragments were not found. Possibly the complex contained a cleavage fragment of C1-INH At and kallikrein (panel 1). A low mol wt band in the C$\bar{1}$-INH Bo preparation (panel 2, lane 2) is an unidentified contaminant, reported earlier.[8] Although C$\bar{1}$-INH Bo failed to form a stable complex with kallikrein, it was cleaved by the enzyme (lane 4). There was no apparent interaction between C$\bar{1}$-INH Mo and kallikrein (panel 3).

avoid aggregation of proteins. After electrophoresis, C$\bar{1}$-INH from subject At appeared to form a lower mol wt complex than would be predicted with plasma kallikrein (Fig 3, lanes 3 and 4, panel 1). In contrast, C$\bar{1}$-INH from Bo was cleaved into multiple visible lower mol wt cleavage fragments during incubation with kallikrein but did not form a stable, higher mol wt complex (Fig 3, panel 2). C$\bar{1}$-INH from subject Mo apparently failed to interact with the kallikrein, even in excess (Fig 3, panel 3). C$\bar{1}$-INH Da also exhibited lower mol wt cleavage fragments when incubated with a molar excess of kallikrein (not shown). Thus under comparable conditions the dysfunctional proteins were heterogeneous in their susceptibility to cleavage by kallikrein. In earlier studies, C$\bar{1}$-INH We formed a complex with plasmin and was also readily cleaved by this protein.[8] This protein was also cleaved by plasma kallikrein but only into a single cleavage product of approximately 96,000 mol wt.

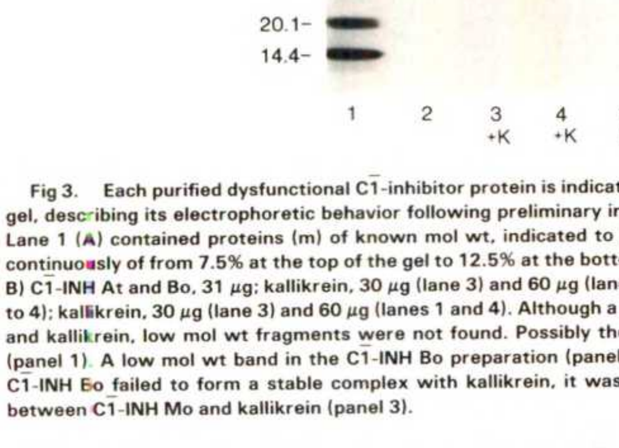

Fig 4. Comparison of electrophoretic behavior of dysfunctional C$\bar{1}$-INH At, Bo, and Za with C1$\bar{s}$ in SDS polyacrylamide gels of 7.5% concentrations (ungraded). C$\bar{1}$-INH was used in molar excess with respect to C1$\bar{s}$: C$\bar{1}$-INH At in an amount of 22.5 μg; C$\bar{1}$-INH Bo (lanes 4, 5), 25 μg, and Za (lanes 7, 8), 55 μg. C1$\bar{s}$, 7.5 μg in all mixtures. The anode is down. Even though C1-INH At was clearly cleaved into lower mol wt fragments by C1$\bar{s}$, two high mol wt complex bands stable in SDS were also formed. C$\bar{1}$-INH Bo, which failed to interact with kallikrein in the experiment in Figure 3, did form a small amount of stable complex with C1$\bar{s}$. C$\bar{1}$-INH Za and C1$\bar{s}$ formed two high mol wt bands, but the source of the two bands is not clear.

Interaction of C1$\bar{s}$ with dysfunctional C$\bar{1}$-INH. When dysfunctional C$\bar{1}$-INHs from At, Bo, and Za were examined in 7.5% polyacrylamide gels, C$\bar{1}$-INH At formed two high mol wt complexes with C1$\bar{s}$, and lower mol wt cleavage fragments evolved (Fig 4, lane 2). C$\bar{1}$-INH Bo and Za also formed high mol wt complexes with C1$\bar{s}$, whereas neither did so with kallikrein. The mol wt of the major C$\bar{1}$-INH Za complex with C1$\bar{s}$ was lower than that formed with C$\bar{1}$-INH Bo but about the same as the lighter complex between C$\bar{1}$-INH At and C1$\bar{s}$. Cleavage of dysfunctional C$\bar{1}$-INH Ta and We by C1$\bar{s}$ was observed in studies reported earlier.[8]

We have not detected cleavage fragments of less than 96,000 mol wt in SDS gels when normal C$\bar{1}$-INH has been exposed to C1$\bar{s}$. The interactions of each of these C$\bar{1}$-INH proteins with C1$\bar{s}$ and kallikrein are compared in Table 1.

DISCUSSION

When normal C$\bar{1}$-INH, which was a doublet in SDS-polyacrylamide gel electrophoresis, was incubated with kallikrein and then subjected to electrophoresis in the same gel system, a major high mol wt complex of about 185,000 to 190,000 mol wt could be visualized (Fig 1A), but only the component of C$\bar{1}$-INH having a mol wt of approximately 106,000 formed stable complexes with kallikrein. The lower mol wt band in the C$\bar{1}$-INH preparation (approximately 96,000) did not do so (Figs 1A and 2). When increasing amounts of C1$\bar{s}$ were incubated with the same preparation of C$\bar{1}$-INH before electrophoresis in graded concentrations of polyacrylamide, both the lower and higher mol wt components of C$\bar{1}$-INH formed a stable complex with C1$\bar{s}$ (Fig 1B). Therefore the 96,000 mol wt component of normal C$\bar{1}$-INH apparently contained structural requirements for stable complex formation with C1$\bar{s}$ but not with kallikrein. Both enzymes could generate the doublet C$\bar{1}$-INH from a preparation containing a homogeneous single band of protein (Fig 2). Exposure to kallikrein appeared to generate a lower mol wt cleavage fragment than that generated by C1$\bar{s}$ (Figs 1A and 1B), as if kallikrein degraded the protein further than did C1$\bar{s}$. Van der Graaf and his associates also found that a plasma kallikrein preparation, or its light chain failed to form complexes with a lower mol wt form (94,000) of C$\bar{1}$-INH,[16] which may be the same as the lower mol wt C$\bar{1}$-INH seen in the present studies. The fact that some preparations of C$\bar{1}$-INH, which are isolated by the method of Harrison,[9] are in a doublet form implies that the protein may have had contact with C1$\bar{s}$ or kallikrein in vivo, for isolation was carried out in the presence of exogenous inhibitors aimed at preventing cleavage of C$\bar{1}$-INH in vitro. One of us (Harrison), however, has found only a single band of C$\bar{1}$-INH antigen in freshly drawn normal plasma using a monoclonal antibody (MoAb) to C$\bar{1}$-INH in an electroimmunofixation procedure. Harpel and Cooper[17] identified a plasmin-generated cleavage fragment of normal C$\bar{1}$-INH that was initially functional but lost activity without evidence of a further loss in mol wt. Zuraw and Curd recently reported that an inactive fragment of 94,000 mol wt could be released from normal C$\bar{1}$-INH in plasma when kallikrein was activated.[17a]

The interactions of dysfunctional C$\bar{1}$-INH proteins with plasma kallikrein were heterogeneous, and only two of these formed complexes with kallikrein that were stable during electrophoresis in graded concentrations of polyacrylamide containing SDS. Each of these (C$\bar{1}$-INH At and Za) had reduced inhibitory properties directed against the amidolytic activity of plasma kallikrein in studies previously reported[8] (Table 1). Therefore the complexes visualized in these studies may not be associated with effective inhibition of kallikrein by the C$\bar{1}$-INH proteins. Dysfunctional C$\bar{1}$-INH We also had reduced inhibitory properties directed against C1$\bar{s}$ but formed visible complexes with C1$\bar{s}$ (Table 1). C$\bar{1}$-INH Bo was cleaved by the plasma kallikrein into multiple lower mol wt fragments of less than 90,000 mol wt (Fig 3). In earlier studies C$\bar{1}$-INH We was exceedingly susceptible to plasmin cleavage.[8] These observations reinforce the evidence of structural heterogeneity of these dysfunctional proteins. It is likely that point mutations account for many of the alterations in dysfunctional C$\bar{1}$-INH proteins,[18] but in at least one instance (C$\bar{1}$-INH Ta) there is an insertion in a high mol wt cyanogen bromide fragment[19] and in another (C1-INH We) a deletion as well as an insertion.[20]

Three dysfunctional C$\bar{1}$-INH proteins were examined for their interactions with preparations of C1$\bar{s}$, since these had not been tested earlier (Fig 4). One, C$\bar{1}$-INH At, was cleaved by C1$\bar{s}$ (Fig 4), and high mol wt complexes were seen, while two others (C$\bar{1}$-INH Bo and Za) also formed a high mol wt complex with C1$\bar{s}$ but were not cleaved when examined under the same conditions of incubation and electrophoresis. C$\bar{1}$-INH Za formed a stable complex with C1$\bar{s}$ (Fig 4) but not with kallikrein, but it inhibited C1$\bar{s}$ to a lesser degree (19% of normal) than kallikrein (64% of normal) in earlier studies.[8] In this instance, the complex between this C$\bar{1}$-INH and C1$\bar{s}$, the C1$\bar{s}$ does not appear to be inhibited; this is reminiscent of our earlier studies in which noninhibitory complexes between plasmin and some of these dysfunctional C$\bar{1}$-INH proteins (We, Da, Za, and Ri) were identified.

These studies point to the possibility that the C$\bar{1}$-INH found in normal plasma may have more than one point of interaction with plasma kallikrein, some of which are defective in dysfunctional C$\bar{1}$-INH proteins. Since most of the dysfunctional C$\bar{1}$-INH proteins did not form complexes of sufficient stability to be visible in the SDS gels but did provide measurable degrees of inhibition in work previously reported,[8] complexes were probably formed but were dissociated during the procedures used for electrophoretic examination of complexes. Some of the inhibitory activities measured may have been due to trace amounts of normal C$\bar{1}$-INH not distinguished from the dysfunctional forms in these electrophoretic analyses. It is likely that the binding affinity of most of the dysfunctional C$\bar{1}$-INH proteins for plasma kallikrein is considerably less than that of normal C$\bar{1}$-INH, and, with two exceptions, significant amounts of covalently linked complexes were apparently not formed.

Serine proteases cleave inhibitors before forming functionally inhibited complexes.[21-24] Salveson and his associates[24] recently identified cleavage of normal C$\bar{1}$-INH by a preparation of C1$\bar{s}$, comparable to that used in the present experiments, by defining the amino acid sequence of a portion of the cleavage fragment released from the carboxy-terminal side of the reactive site of C$\bar{1}$-INH. Weiss and Engel[25] reported that heparin could enhance cleavage of C$\bar{1}$-INH by C1$\bar{s}$. In our experiments a homogeneous preparation of normal C$\bar{1}$-INH (mol wt approximately 106,000) was cleaved by C1$\bar{s}$ and kallikrein, forming a doublet of which the mol wt of the lighter component was 96,000. Bing and Canar[26] have identified a 90,000 to 92,000 mol wt fragment that could be generated by plasmin. Neither C1$\bar{s}$ nor kallikrein appeared to release a similar fragment in their experiments or those reported here. It is possible that some fragments of C$\bar{1}$-INH of much lower mol wt may have been released from C$\bar{1}$-INH protein during their interactions with kallikrein but were not detected because the heavily glycosylated portions of the molecule may not bind to protein stains.

In Vitro Action of Tumor Necrosis Factor on Myeloid Leukemia Cells

By Reinhold Munker and Phillip Koeffler

We investigated the in vitro action of recombinant tumor necrosis factor alpha (TNF) on the clonal growth of normal and malignant myeloid cells. Clonogenic cells from six of nine myeloid leukemia cell lines were very sensitive to the effects of TNF with 50% of the colonies inhibited (ED_{50}) by concentrations of TNF that ranged between 6 and 150 U/mL. A decrease in DNA, RNA, and protein synthesis and in cloning efficiency occurred within three hours of exposure of HL-60 promyelocytes to TNF. The TNF in combination with recombinant interferons produced an additive or synergistic inhibition of colony formation of HL-60 and THP-1 myelomonoblasts. Normal human CFU-GM are sensitive to TNF (ED_{50} between 100 and 50,000 U/mL), but their sensitivity to TNF depends on the source of colony stimulating factor (CSF) with T lymphocyte derived GM-CSF (recombinant or natural) partially protecting the CFU-GM from the suppression exerted by TNF (and interferons). In eight of 15 cases the clonogenic myeloid leukemia cells from patients with acute or chronic myeloid leukemia were more sensitive than normal CFU-GM using GM-CSF as a source of colony stimulating activity. Further studies showed that the action of TNF on myeloid leukemia cells probably can be only partially explained by differentiation. Our finding of a possible selective cytotoxicity to leukemic clonogenic cells by TNF suggests that TNF may have value in the therapy of some patients with myeloid leukemia.

© 1987 by Grune & Stratton, Inc.

DESPITE recent improvements in chemotherapy and bone marrow transplantation, the prognosis of acute and chronic myelogenous leukemia is unsatisfactory.[1,2] Therefore new drugs and therapeutic possibilities continue to be investigated. Tumor necrosis factor (TNF) was discovered when mice with transplanted tumors developed hemorrhagic necrosis of these tumors when endotoxin was injected after priming with Bacillus calmette guerin (BCG). Activated macrophages were identified as the source of TNF.[3,4] Growth of a variety of mouse and human tumor cells are inhibited by TNF, whereas several types of normal cells from the same species are unaffected after exposure to the protein.[3] Recently the gene for human TNF was cloned and recombinant proteins synthesized.[5-7] We studied the effects of recombinant human TNF on human myeloid clonogenic cells from leukemia cell lines, patients with leukemia, and normal individuals to determine if the proliferation of malignant and normal myeloid progenitor cells is sensitive to this monokine.

MATERIALS AND METHODS

Details and references concerning the myeloid cell lines used in this study are provided in Table 1. The cells were grown in Lux tissue culture flasks in alpha medium (Flow Laboratories, McLean, VA) supplemented with 10% fetal calf serum (FCS). Cells in logarithmic growth were used for plating experiments. Cell concentration and viability were determined by counting the cells at various time points in 0.4% trypan blue (Gibco Laboratories, Chagrin Falls, OH).

Bone marrow was obtained from both healthy volunteers and leukemic patients by aspiration from the iliac crest after written consent was obtained. For anticoagulation, preservative-free heparin (O'Neill, Jones and Feldman, St. Louis) was used. The mononuclear cells were isolated by centrifugation on Ficoll-Hypaque gradients, washed twice in phosphate-buffered saline (PBS), and suspended in alpha medium containing 10% FCS and 1% penicillin-streptomycin (Irvine Scientific, Irvine, CA). Prior to use in plating experiments the light density bone marrow cells from normal volunteers were incubated for 90 minutes on plastic surfaces in a humidified, 5% CO_2, 37°C incubator to deplete adherent cells. Peripheral blood mononuclear cells were obtained from leukemia patients using similar techniques. Details concerning the leukemia patients are provided in Table 2. Bone marrow and peripheral blood samples contained more than 90% leukemic cells as determined by morphology. Leukemia cells from all patients with chronic myelogenous leukemia contained the Philadelphia chromosome.

Reagents. Recombinant human tumor necrosis factor[5] was generously provided by Genentech, San Francisco, and was stored at 4°C (1 mg corresponds to 3.7×10^7 U). Before use, dilutions in tissue culture medium containing 10% FCS were made. Recombinant interferons were kindly provided as follows: alpha interferon (1.8×10^7 U/mL) by Hoffmann-La Roche, Nutley, NJ; beta interferon (1 mg = 45×10^6 U) by Cetus, Emeryville, CA; gamma interferon (2 to 3×10^7 U/mg) by Genentech, San Francisco.

Colony formation in soft agar. Cells were plated in Lux culture dishes (Miles Lab, Naperville, IL) in a two-layer soft agar system according to previously described methods.[17] The underlayer contained 0.5% agar, the upper layer 0.3% agar (Difco, Detroit). The culture medium was alpha medium. The TNF and, if appropriate, CSF were mixed into the lower layer. Several sources of CSF were used: conditioned medium from a human T lymphocyte line (MO)[18]; human placenta conditioned medium (CM) day 6 [prepared as described by Burgess et al[19]; recombinant human GM-CSF[20] was provided by Dr J.C. Gasson; GCT-conditioned medium[21] was kindly provided by Drs J. Di Persio (UCLA) and C. Abboud (University of Rochester); Dr L. Souza (Amgen, Thousand Oaks, CA) generously provided recombinant G-CSF.[22] All sources of CSF were tested at different concentrations and used at the optimal dose: 5% CM for placental and GCT-conditioned medium, 4% to 5% CM for Mo; 100 pM for recombinant GM-CSF; 25 ng/mL for recombinant G-CSF. The FCS used was prescreened for low background colony formation

‡Monoblast and erythroblast characteristics

and high stimulation with CSF. For normal human bone marrow and leukemic cells, 2 × 10^5 cells were plated per dish. Myeloid cell lines were plated at 1,000 to 5,000 cells per dish. The plating efficiency varied between 5% (KG-1) and 38% (K562). The KG-1 cell line (passage 28) formed colonies only in the presence of CSF. Cultures were placed in a humidified atmosphere, 5% CO$_2$, 37°C. Normal CFU-GM (colonies of ≥40 cells) and leukemic colonies (aggregates of ≥20 cells) were scored after ten days with an inverted microscope. All experiments were performed using triplicate or quadruplicate plates per experimental point.

In some experiments HL-60 cells were incubated with different concentrations of TNF (20, 50, 500, and 5,000 U/mL) for various time points and were washed extensively. The number of surviving cells was determined by counting in trypan blue solution. At each time point 2,000 viable cells/plate were seeded. Depending on the concentration of TNF (5,000 to 20 U/mL), 12% to 97% of the cells survived a 24-hour incubation compared to control cultures. To demonstrate the specificity of the effects of TNF, 20,000 U were incubated at room temperature with 20 μg of neutralizing monoclonal antibody (MoAb) against TNF (kindly provided by Dr C. Nelson, Genentech, San Francisco) for 90 minutes and then used in plating experiments as described.

Abbreviations: AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia; myBC, myeloid blast crisis; PB, peripheral blood; BM, bone marrow.

*Number of colonies per 2 × 10^5 cells plated in dishes not containing TNF.

†50% inhibitory concentration of TNF.

‡Less than 50% inhibition at 10,000 U/mL of TNF.

DNA, RNA, and protein synthesis. The DNA synthesis was studied by exposing TNF-treated cells (10^6/mL) to 0.5 μCi methyl ^{3}H-thymidine (NEN, Boston) for 90 minutes in multiwell tissue culture plates (quadruplicate wells per point) in a humidified atmosphere with 5% CO$_2$. The cells were harvested with a MASH-harvester, and isotope uptake was determined with liquid scintillation photometry (Beckman [S1800]). The RNA synthesis was studied by labeling TNF-treated cells (10^6/mL) with 0.5 μCi ^{14}C-uridine (UdR) for two hours at 37°C (triplicate wells per point), washing the cells twice in PBS, precipitating the cells on ice with 5% trichloroacetic acid (TCA) for ten minutes, washing twice with 5% TCA, and heating for 60 minutes at 80°C. A 200 μL aliquot from each sample was mixed with Aquasol (NEN, Boston) and counted in a scintillation photometer. Protein synthesis was determined by suspending the cells (75,000 cells per microtiter well) in methionine-free Earle's medium (Gibco, Grand Island, NY) with 5% FCS and exposing the cells to 1 μCi ^{35}S-methionine for 90 minutes. Protein synthesis was determined as described for DNA synthesis. The results for DNA, RNA, and protein synthesis were corrected for cell loss during incubation with TNF.

NBT reduction, nonspecific esterase cytochemistry. For NBT reduction, cells were mixed with an equal volume of a solution containing 1.25 mg/mL NBT (Sigma, St. Louis), 17 mg/mL bovine serum albumin and 1 μg/mL 12-0-tetradecanoylphorbol 13-acetate (Miles) for 30 minutes in 37°C incubator with 5% CO$_2$; washed in PBS, cytocentrifuged; fixed in methanol; and stained with Giemsa solution. For cytochemistry the cells were stained for alpha-naphthyl-acetate esterase (ANAE), according to routine hematologic methods (kindly performed by Dr F. Naiem, UCLA Dept of Pathology).

Statistical comparisons. We define synergism to mean the proportion of colony growth in the presence of TNF and IFN < (proportion of colony growth in the presence of TNF alone) × (proportion of colony growth in the presence of IFN alone). Therefore synergism may be evaluated by comparing the logarithm of colony growth in the presence of TNF and IFN to the sum of the logarithms of growth in TNF alone and IFN alone. For statistical analysis we made graphic comparisons and used Student's *t* test to detect synergism at combinations of TNF and interferons and for the comparison of different points (analysis kindly performed by Dr D. Heitjan, UCLA Dept of Biomathematics).

RESULTS

Clonal proliferation of cells from six of nine myeloid leukemia cell lines was inhibited by recombinant TNF (Fig 1, Table 1, mean values of at least three independent experiments). The concentration required for a 50% inhibition of colony formation in soft agar (ED$_{50}$) varied between 6 and 150 U/mL. Colony formation of sensitive lines was inhibited almost 100% at 1,000 U/mL. Cell lines that did not reach a 50% inhibition at 10,000 U/mL TNF nevertheless were still clearly inhibited at this concentration. The effects observed are due to TNF since a preincubation with a neutralizing MoAb could prevent 97% ± 2% (±SD) of the inhibition of HL-60 cells (data not shown). In further experiments we exposed HL-60 to TNF for different periods of time, washed thoroughly the cells three times, counted viable cells, and plated them in soft agar. The cloning efficiency was drastically reduced after a short exposure to TNF (Fig 2). For example, after a three-hour exposure

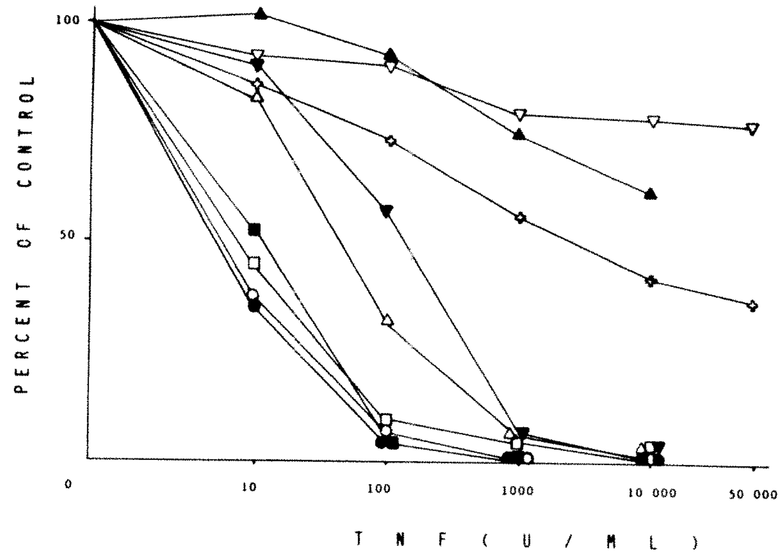

Fig 1. Effect of tumor necrosis factor on clonal growth of cells from myeloid lines. HL-60 (●), HL-60 variant (O), KG-1 (△), KG-1A (▼), EM-3 (□), U937 (■), HEL (✣), THP1 (▽), K562 (▲). Results are expressed as a percent of colonies in control dishes not containing TNF; each point represents the mean of three to seven experiments with triplicate plates per experiment.

(37°C) to 50 U/mL TNF, greater than 75% of colonies from HL-60 were inhibited. The lowest concentrations of TNF (20 U/mL) caused a less pronounced decrease in cloning efficiency than the other concentrations tested. After 24 hours a partial recovery in the cloning efficiency was observed, which may be due to lysis of the colony-forming cells most sensitive to TNF. Similar results were observed with pulse exposure of the cells to TNF at either 23°C or 4°C (data not shown).

We tested the potency of the combination of recombinant interferon and recombinant TNF on clonal inhibition of leukemic cell lines. A cell line that was relatively insensitive to TNF (THP1 myelomonoblasts) was cultured in the presence of TNF (0 to 50,000 U/mL) and either α, β, or γ recombinant interferons (0 to 5,000 U/mL). A synergistic interaction between TNF ($\geq$100 U/mL) and interferons could be observed at concentrations of either α or β interferon at $\geq$500 U/mL, and γ interferon at $\geq$1,000 U/mL. Figure 3A shows the results for the combination experiments with 5,000 U/mL of either α, β, or γ interferon and 0 to 1,000 U/mL TNF using THP1 as test cells. In contrast, TNF and γ interferon separately cultured with HL-60 in soft agar markedly inhibited clonal growth, but combinations of TNF and γ interferon produced only an additive inhibition of clonal growth of HL-60 (Fig 3B). The clonal growth of another cell line (HEL) was moderately inhibited by TNF but not by interferons; combinations of these agents neither caused additive nor synergistic inhibition of clonal growth of HEL cells (data not shown).

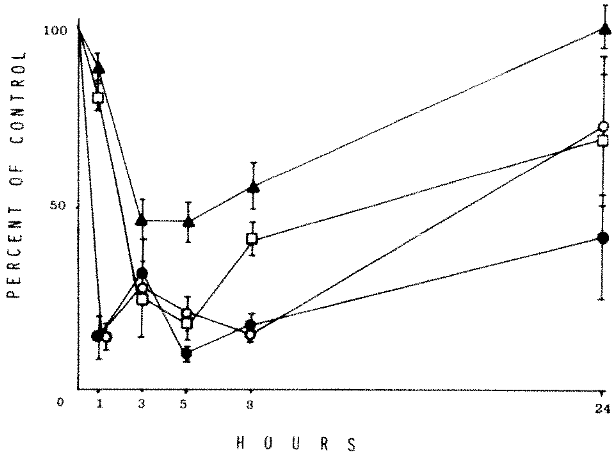

Fig 2. Pulse exposure of HL-60 cells to tumor necrosis factor. The cells (10^6/mL) were exposed to 20 (▲), 50 (□), 500 (O), 5,000 (●) U/mL TNF for the indicated time, washed, and 2,000 viable cells per point were plated in quadruplicate. Colonies were counted after ten days. Each point represents the mean ± SD of two experiments.

Low doses of TNF (20 U/mL for six days) induced a partial differentiation of the HL-60 line with 25% of cells developing the ability to reduce NBT and 8% of cells staining positively with ANAE, an enzyme that is found in monocytes and macrophages. The viability of the cells on day 6 of culture was $\geq$90%. The TNF was unable to induce differentiation of KG-1 myeloblasts or HL-60 variant blast cells.

Fresh leukemia cells from 12 of 15 patients with myeloid leukemia were sensitive to TNF in the clonogenic assay for leukemic cells, with an ED_{50} in the range of 20 to 2,500 U/mL (Table 2, Fig 4). The cells of four of five cases of AML, five of six cases of CML in chronic phase, and three of four cases of CML in myeloid blast crisis responded to TNF with a clonal inhibition. No obvious correlation between the in vitro response to TNF and the induction of remission or survival could be observed in the 13 patients in whom follow-up was available. We tested CFU-GM from nine normal donors and found that TNF also suppressed normal myeloid progenitors (Fig 5). However, the degree of suppression strongly depended on the source of colony stimulating factor used in the assay. In plates containing 10,000 U TNF/mL, a suppression of 53% was observed with MoCM (CM from HTLV-II-infected T lymphocyte line), 48% with recombinant GM-CSF, 97% with placental-conditioned medium, 98% with GCT-CM (CM from sarcoma line), and 100% with recombinant G-CSF. The 50% inhibitory concentration (ED_{50}) varied between 100 U/mL (recombinant G-CSF) and 50,000 U/mL (recombinant GM-CSF). (See

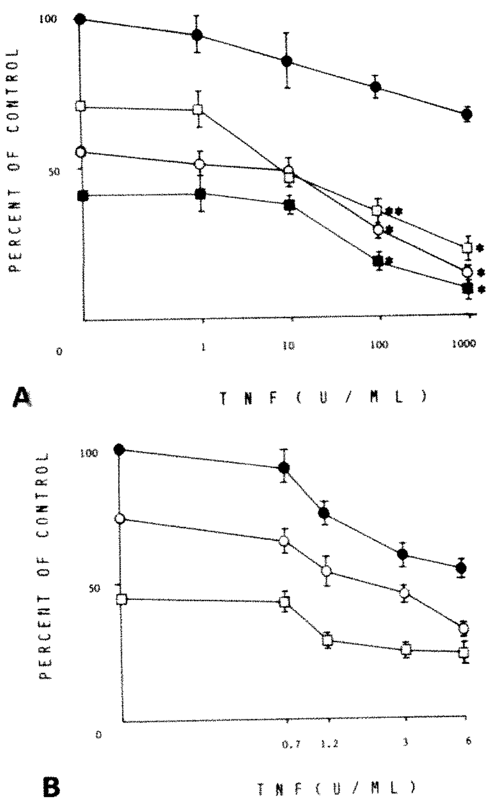

Fig 3. Effect of tumor necrosis factor and interferon on leukemic colony formation. (A) The THP1 myelomonoblast line was grown in soft agar with different concentrations of TNF alone (●) or in combination with recombinant interferons (5,000 U/mL alpha interferon [○], 5,000 U/mL beta interferon [■], 5,000 U/mL gamma interferon [□]). Synergistic inhibition is shown by one ($P \leq 0.01\%$) or two ($P \leq 0.05\%$) asterisks. The effects of IFN alone are provided at the 0 concentration. (B) The HL-60 promyelocyte line was grown in soft agar with TNF alone (●) or in combination with recombinant gamma interferon (8 U/mL [○], 24 U/mL [□]). Results for 3A and 3B are expressed as a mean percent of colonies formed in experimental plates as compared to control dishes not containing TNF or interferon; each point represents the mean ± SD of four experiments performed with triplicate plates. The effects of interferon alone are shown at the 0 concentrations of TNF.

Fig 5 for details of the inhibition curves). The TNF dose-response curves of normal human GM-CSF stimulated with conditioned medium from a HTLV-1-infected T lymphocyte line (SLB-1)[23] as a source of CSF was similar to recombinant GM-CSF and MoCM (data not shown).

We also studied the effect of combinations of recombinant α, β or γ interferons with TNF on normal committed myeloid progenitors (Table 3). In the presence of T cell-derived GM-CSF, little inhibition was observed with interferons alone or in combinations with TNF. Using either placental conditioned medium or recombinant G-CSF as sources of colony stimulating activity, the interferons were clearly inhibitory, and the addition of TNF produced an additive or synergistic effect (especially at 100 U TNF/mL).

We examined DNA, RNA, and protein synthesis in HL-60 cells in liquid culture after exposure to TNF (20 to 500 U/mL) (Fig 6). A dose-dependent decrease in all parameters was observed with increasing concentrations of TNF, with a significant ($P < 0.05$) decrease in all three parameters occurring within two hours of exposure of the cells to TNF.

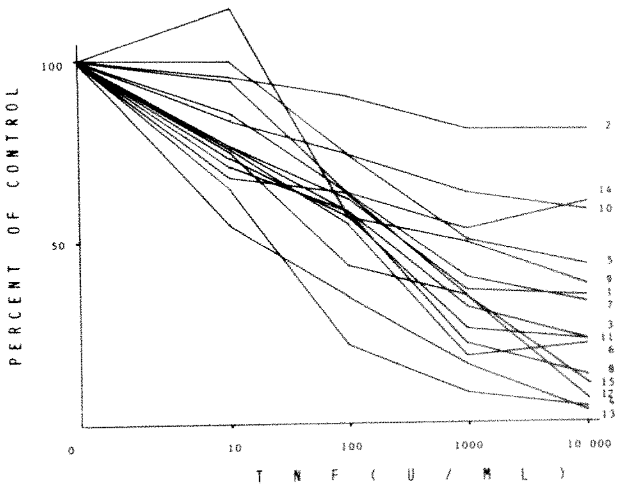

Fig 4. Effect of tumor necrosis factor on clonal growth of myeloid leukemic cells from patients. Results are expressed as a mean percent of colonies formed in experimental plates as compared to control dishes not containing TNF. Each point represents the mean of triplicate plates. Numbers on the right correspond to the patient numbers in Table 2.

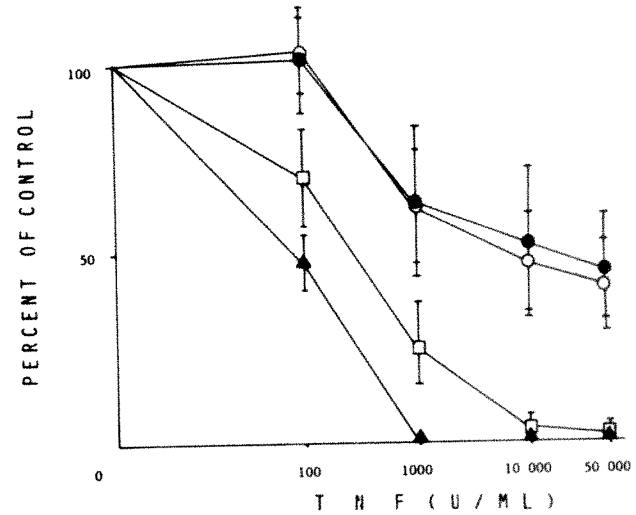

Fig 5. Effect of tumor necrosis factor on the clonal growth of CFU-GM from bone marrow of normal donors. 2 × 10^5 light density bone marrow cells (depleted of adherent cells) were plated in soft agar with various concentrations of TNF and different sources of colony stimulating factors (-0-Mo CM [5%], n = 9 donors, 153 ± 27 colonies/control plates containing no TNF; recombinant GM-CSF [●], 100 PM, n = 7 donors, 162 ± 29 colonies/control plates; placental-conditioned medium [□], 5%, n = 5 donors, 155 ± 30 colonies/control plates; recombinant G-CSF, 25 ng/mL [▲], n = 4 donors, 170 ± 15 colonies/control plates). Results are expressed as a mean percent (± SD) of colonies formed in experimental plates as compared to control dishes not containing TNF. Each experiment was performed with quadruplicate plates per point.

Table 3. Effects of Interferons, TNF, and Combinations of TNF and Interferons on Normal Myeloid Progenitors (CFU-GM)

Source of Colony Stimulating Factor	Concentration and Type of Interferon	Colony Formation (% of Control Plates without TNF or Interferons) Concentration of TNF 0	10	100 U/mL
MoCM	0 Interferon	100%	96% ± 7%	98% ± 5%
	1000 U/mL α IFN	88% ± 10%	92% ± 6%	90% ± 5%
	2000 U/mL β IFN	103% ± 5%	96% ± 12%	91% ± 9%
	1000 U/mL γ IFN	93% ± 11%	95% ± 8%	90% ± 12%
PCM	0 Interferon	100%	92% ± 10%	71% ± 15%
	1000 U/mL α IFN	70% ± 15%	53% ± 4%	20% ± 8%*
	1000 U/mL β IFN	83% ± 4%	77% ± 12%	34% ± 18%
	1000 U/mL γ IFN	69% ± 11%	51% ± 8%	13% ± 4%*
Recombinant G-CSF	0 Interferon	100%	74% ± 16%	45% ± 8%
	1000 U/mL α IFN	49% ± 10%	38% ± 5%	7% ± 6%*
	1000 U/mL β IFN	60% ± 12%	41% ± 15%	8% ± 5%*
	1000 U/mL γ IFN	33% ± 2%	23% ± 5%	3% ± 2%*

Soft agar cultures were performed as described in "Materials and Methods." Results are mean (±SD) of four experiments and are expressed as percent of control cultures without TNF or interferon. In control cultures with MoCM 149 ± 23 colonies, in control cultures with PCM 158 ± 30 colonies, and in control cultures with recombinant G-CSF 170 ± 15 colonies per plate were observed.

Abbreviations: CM, conditioned medium; PCM, placental conditioned medium, recombinant G-CSF.

*Synergistic inhibition ($P \leq 0.05\%$).

DISCUSSION

Our results suggest that TNF is inhibitory in vitro against most myeloid leukemia clonogenic cells from established lines and from patients. Recombinant TNF was recently shown to have an antiproliferative effect on seven of 22 nonhematopoietic human tumor lines, whereas five normal human diploid lines were enhanced in their growth when cultured with TNF.[24] We confirm here studies by others that TNF is inhibitory for normal CFU-GM.[25,26] Differences between investigators in the concentrations of TNF that suppress proliferation are at least partially due to how the unitage of TNF was originally determined (eg, in the presence or absence of Actinomycin D). We observed a synergistic inhibition of CFU-GM when α- and γ-interferons were combined with TNF in the presence of placental CM and recombinant G-CSF (β interferon was synergistic only in combination with G-CSF). Earlier studies showed that interferons are potent inhibitors of myeloid progenitors.[27,28] Furthermore, Broxmeyer et al[26] found synergism between TNF and γ-interferons, but not between TNF and α-interferons using normal marrow target cells. Why the results of studies by Broxmeyer et al[26] and us differ when examining the combined effects of α-interferon and TNF might relate to differences in concentrations of α-interferon or in the source of CSF used in the two studies. A new finding of this investigation is that the source of CSF determines the degree of suppression by TNF. A strong suppression of myeloid colonies by TNF occurs in the presence of recombinant G-CSF or conditioned from placenta and the GCT cell line; T lymphocyte derived GM-CSF (recombinant and natural) partially protects the myeloid progenitors from the inhibitory effects of TNF. We also observed a similar protection of myeloid colony formation by T lymphocyte derived GM-CSF against the suppressive influences of interferons.

Further studies are required to determine the mechanism

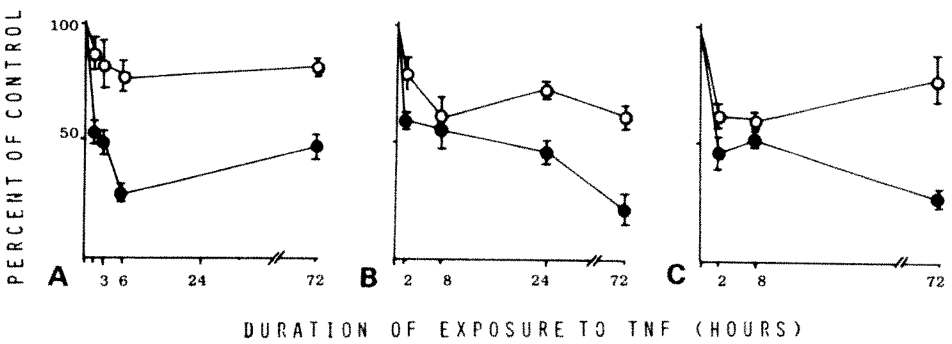

Fig 6. Influence of tumor necrosis factor on DNA, RNA, and protein synthesis of HL-60 cells. The HL-60 cells were incubated with TNF (25 [○] and 500 [●] U/mL for DNA synthesis and 20 [○] and 300 [●] U/mL for RNA and protein synthesis), for the indicated time periods, washed, and labeled with radioactive precursors. Results are expressed as a mean percent value in experimental dishes as compared to control dishes containing no TNF. Each point represents the mean of three experiments performed with quadruplicate cultures. (A), DNA-synthesis; (B), RNA-synthesis; (C), protein synthesis.

by which T lymphocyte derived GM-CSF partially reverses the inhibitory action of TNF; (eg, a direct interaction with the TNF protein, competition for the TNF receptor, stimulation of a clonogenic myeloid progenitor cell that is partially resistant to TNF, stabilization of protein kinase C).

The mechanism of inhibition of proliferation of clonogenic leukemia cells mediated by TNF is unclear but probably is not completely linked to differentiation, since several of the most sensitive myeloid lines (KG-1, HL-60 blasts) were not induced to differentiate when exposed to TNF. Approximately 25% of HL-60 cells differentiated after a six-day exposure to TNF (20 U/mL). Takeda et al[29] have provided evidence that TNFα is the same as a previously reported protein known as differentiation inducing factor, which can induce differentiation of HL-60 cells. Recently receptors for TNF were demonstrated on the surface of several cell types.[24,30,31] However, the presence of TNF receptors on the cell does not necessarily predict that a cell will be sensitive to TNF, since a TNF resistant cell line has been reported with approximately the same number of TNF receptors as a cell line sensitive to the cytotoxic effects of TNF.[24] The synergism of TNF with gamma interferon, which was originally observed by Williamson et al[31] and which we found for THP1 myelomonoblast cells, may be due to an increase of the number of TNF receptors as has been reported for a cervical carcinoma cell line.[32] We also observed that the cloning efficiency and the DNA, RNA, and protein synthesis of HL-60 cells decreased within two hours of exposure to TNF, suggesting that TNF very rapidly affects vital cellular functions.

When we compared the inhibition of leukemic clonogenic cells with the inhibition of normal CFU-GM using T cell derived GM-CSF, in eight of the 15 cases (two AML, three CML in the chronic phase, and three cases in blast transformation), the leukemic cells were more sensitive than the mean ± SD of normal CFU-GM.

The reason why most malignant myeloid cell populations are sensitive to the growth inhibiting action of TNF and why normal myeloid cells may be less sensitive is unclear. Possibilities include differences in affinity or number of TNF receptors, differences in the ability to translocate TNF across the cell membrane, alteration in critical cellular substrates needed for the action of TNF, or ineffective repair mechanisms in the neoplastic cells. Our in vitro results should be interpreted with caution, since we did not prove that all in vitro cell aggregates in the soft agar cultures were derived from the malignant clone and since the in vitro clonogenic cells may not be true tumor stem cells in vivo.[24] Nevertheless TNF may possibly have value in the therapy of patients with myeloid leukemia. In vitro studies with leukemic clonogenic cells may help to identify these patients. The potential toxicity of TNF, including myelotoxicity, must be carefully evaluated, since TNF or a closely related molecule was found to mediate a variety of adverse effects in mice.[33,34]

Fetal Hemoglobin-Containing Cells Have the Same Mean Corpuscular Hemoglobin as Cells Without Fetal Hemoglobin: A Reciprocal Relationship Between Gamma- and Beta-Globin Gene Expression in Normal Subjects and in Those With High Fetal Hemoglobin Production

By G.J. Dover and S.H. Boyer

We have developed methodology that allows comparison of the mean corpuscular hemoglobin (MCH) of fetal hemoglobin (HbF)-containing red cells (F cells) with the MCH of non-F cells from the same individual. To do this, suspensions of peripheral blood erythrocytes and their internal contents are fixed with an imidodiester, dimethyl-3,3'-dithiobispropionimidate dihydrochloride (DTBP). Thereafter fixed cells are made permeable to antisera by treatment with Triton X-100 and isopropanol, reacted with a mouse monoclonal antibody (MoAb) against HbF, and then with fluorescein-conjugated antimouse IgG. No appreciable hemoglobin is lost during such manipulation. Red cells from a diversity of subjects were thus treated and examined microscopically, first by transmitted light and then by epifluorescence. A direct correlation between Coulter-derived MCH and mean absorbance of 415 nm transmitted light was found for 100 unfixed ($r = 0.96$) and for 100 antibody-treated fixed-permeabilized red cells ($r = 0.99$) among individuals selected so as to provide a range of Coulter MCH values between 20 and 35. Comparisons of microscopically derived MCH of F cells and non-F cells were statistically nondistinguishable ($P > 0.05$) in all subjects. Such comparisons included normal individuals (less than 1% F cells), SS patients (7% to 48% F cells), subjects with congenital anemia (22% to 65% F cells), individuals with heterocellular hereditary persistence of HbF (HPFH) (12% to 21% F cells), and heterozygotes for beta$^+$ thalassemia (11% to 31% F cells). We conclude that gamma- and beta-globin production within F cells is regulated in a reciprocal fashion both among normal individuals and among individuals with elevated HbF production.

© 1987 by Grune & Stratton, Inc.

THROUGHOUT normal adult erythropoiesis, hemolysate fetal hemoglobin (HbF) persists at a low level of usually less than 2.0%. This small amount of HbF is restricted to a subpopulation of erythrocytes, termed F cells.[1] F cells contain both HbF and adult hemoglobin (HbA). While the amount of HbF within F cells has been directly measured and found to range from 3 to 8 pg HbF/F cell,[2] it is not known whether the mean corpuscular hemoglobin (MCH) of F cells is greater than that of non-F cells from the same individual. Hence it is not clear whether F cells are (1) formed as a result of HbF being superimposed upon HbA content with the result that the MCH of F cells would become greater than that of non-F cells, or (2) the MCH is held constant among F cells and non-F cells in any one individual. The latter observation, if true, would suggest that HbF and HbA content is reciprocally regulated within F cells. In this report we introduce new methodology to compare the MCH of F cells and non-F cells. We find that F cells and non-F cells have equal MCH, both in normal adults and in individuals with increased HbF production.

MATERIALS AND METHODS

Subjects. EDTA anticoagulated blood was obtained from normal persons, from patients with sickle cell (SS) disease, and from individuals with hereditary persistence of HbF (HPFH), beta$^+$ thalassemia, or congenital anemia (Fanconi's anemia and Diamond-Blackfan anemia).

Red cell fixation. Prior to fixation, 0.5 mL whole blood was washed once with 3 mL phosphate-buffered saline PBS (20 mmol/L sodium phosphate, pH 7.4, 0.13 mol/L NaCl) and twice with 3 mL 0.125 mol/L borate-saline, pH 8.37.[3] To cross-link erythrocyte proteins and thus fix cells,[4,5] 0.1 mL of ice-cold borate saline containing 50 mg/mL dimethyl-3,3'-dithiobispropionimidate dihydrochloride (DTBP) (Pierce Chemicals, Rockford, IL) was added to 1 mL washed cell suspension having an approximately 3% hematocrit and the mixture gently rotated in a capped 1.5 mL polypropylene Eppendorf tube (Brinkman Instruments, Westbury, NY) for 30 minutes at 37°C. Thereafter unreacted DTBP was consumed by introducing the mixture into a 12 × 75-mm glass tube containing 2 mL ice-cold 62 mmol/L diethanolamine in borate saline. After brief mixing cells were pelleted by 30-second centrifugation at 1,000 × g and resuspended in 4 mL of the 62 mmol/L diethanolamine solution. Five minutes later fixed cells were recovered by centrifugation and resuspended in 2 mL PBS containing 3% bovine serum albumin and 0.025% NaN_3. To preclude later cell clumping, 1-mL aliquots of the resuspension were briefly vortexed just before storage at −85°C.

Red cell permeabilization. Ten microliters of a thawed suspension of fixed cells, containing approximately 10^6 erythrocytes, were introduced into a 1.5 mL polypropylene Eppendorf tube filled with a Millipore-filtered (Bedford, MA) solution of scintillation-grade 0.8% Triton X-100 (Research Products International, Elk Grove, IL) in PBS. After two to five minutes, cells were centrifuged for 12 seconds in a model 5413 Eppendorf centrifuge. Following careful removal of supernatant, 0.5-mL filtered 2.5% Triton X-100 in PBS was added and cells quickly resuspended by 10- to 15-second vortex mixing. So as to permeabilize cells further, 0.5 mL isopropanol was immediately added, tube contents were again vortex mixed for a few seconds, and the suspension was at once centrifuged for 30 seconds at 1,000 × g in a Clay-Adams Sero-Fuge II (Parsippany, NJ). The desired result was to deposit erythrocytes as an even band along the side of the tube, thereby avoiding unwanted clumping. After supernatant removal, cells were vortex mixed with 1 mL filtered 0.8% Triton X-100 in PBS and recovered by 12-second centrifugation in

the Eppendorf centrifuge. Thereafter cells were resuspended in a residual supernatant volume of about 20 μL. If fixed permeabilized cells had been seen to clump during centrifugation in the Clay-Adams device, or if they were to be examined by flow cytometry, they were briefly sonicated using a cup sonicator (Heat Systems-Ultrasonics, Plainview, NY) set at maximum output until any clumps had visibly dispersed.

Monoclonal anti-HbF and immunofluorescent staining of cells. Monoclonal antibodies (MoAbs) against HbF, purified from an individual with homozygous pancellular HPFH,[6] were developed from a Balb/c mouse given (1) 100 μg of a 3:1 (wt/wt) HbA:HbA$_2$ mixture on the day of birth, in an attempt to induce tolerance to these antigens; and (2) beginning at age 4 weeks, seven intraperitoneal injections of 0.4 to 0.75 mg HbF plus Freunds adjuvant over a 10-month period. Antisera obtained just before sacrifice reacted with HbA, albeit less well than with HbF. Two days after the last injection of HbF, polyethylene glycol 4,000 (Merck, Dormstadt, Germany) was used to fuse 10^8 spleen cells from the immunized mouse with 10^8 SP2/0-Ag14 mouse myeloma cells.[7] Two weeks after seeding in the presence of peritoneal macrophages and after beginning selection with hypoxanthine-aminopterin-thymidine,[8,9] hybridomas were found in 48% of 960 culture wells. Media from the 50 wells with the most rapidly propagating cells were screened for reactivity with CO-HbF and CO-HbA affixed to Immulon (Dynatech Laboratories, Alexandria, VA) surfaces of 96-well plates. Eleven anti-HbF clones were detected following reaction with alkaline phosphatase-coupled anti-antibody. Ten of these clones reacted better with HbF than with HbA. Ascites fluids from pristane-primed mice[8,9] injected with semisoft agarose-derived subclones from one of these hybridomas, termed 15-3.1, persistently reacted at least 100-fold better with HbF than with equivalent quantities of HbA. 15-3.1 is a sturdy cell line that grows readily in culture, remains reproducible in its anti-HbF production, and has resisted loss during repeated episodes of freezing-thawing over a 5-year period. However, the affinity of the anit-HbF thus produced is comparatively low, and, while it binds readily to excesses of immobilized HbF, it reacts poorly with trace levels of HbF in solution and therefore cannot be utilized in conventional radioimmunoassays.

For F-cell identification, 20 μL of a suspension of fixed and permeabilized cells was reacted with 50 μL of 15-3.1 in the form of mouse ascites fluid containing 25 mg/mL protein and about 5 mg/mL anti-HbF. After 15-minute incubation at room temperature with periodic agitation, cells were twice washed with 1 mL filtered 0.8% Triton X-100 in PBS using an Eppendorf centrifuge. Recovered cells were then reacted with 50 μL of 0.8 mg/mL Fluorescein-conjugated F(ab')$_2$ fragment of affinity-purified rabbit antimouse IgG (Cooper Biomedical, Westchester, PA). After a 15-minute reaction in the dark, cells were twice washed with 1 mL filtered 0.8% Triton X-100 in PBS. For microscopy, cells were suspended in a solution composed of 1 vol 10 mg/mL p-phenylenediamine (Sigma, St. Louis) in PBS and 9 vol glycerol[10] and mounted on glass microscope slides under cover slips sealed with fingernail polish.

Determination of absorbance of 415 nm light by individual F cells and non-F cells. A Zeiss universal microscope equipped for both transmitted light and epifluorescence, a rapid shutter mechanism, and a photomultiplier interfaced to a Hewlett Packard 9825A computer was used for all microscopic measurements. Light from a 100 W mercury lamp was transmitted through a 415 ± 9 nm band pass filter (Infrared Industries, Waltham, MA), and the light absorbance for 100 individual red cells was measured at 500X using a Zeiss 25X Neofluar immersion objective. For each cell the light absorbance was measured in a circular field 10 μm in diameter. Background light absorbance from an adjacent field, free of cells, was subtracted from each measurement. Paired observations for the cell and background were stored and collated in the computer. Background light was kept uniform between slides by manipulation of the microscope condenser and normalization of photomultiplier output from an empty field, thereby ensuring reproducible measurements. In assays where comparisons of 415 nm light absorption from F cells and non-F cells were to be made, each cell was also viewed under >520 nm emitted epifluorescence so as to distinguish between F cells and non-F cells.

The percentage of F cells was separately determined for each sample by estimating the proportion of fluorescent cells found among 500 fixed and permeabilized erythrocytes. In addition, suspensions of fluorescent-labeled cells were analyzed in an Ortho Cytofluorograf (Ortho Instruments, Boston) equipped with 0.8 mW helium-neon and 100 mW argon lasers. Percent HbF in whole blood hemolysates was measured by alkali denaturation.[11] The number of alpha-globin genes in subjects with SS disease and microcytosis was determined via restriction enzyme analysis of DNA derived from peripheral blood leukocytes.[12] Statistical analysis of the difference between MCH of F cells and non-F cells was performed by testing the null hypothesis with Student's *t* test.

RESULTS

HbF detection with monoclonal anti-HbF. For a variety of subjects, measurements of the percentage of F cells, as determined by visual enumeration of fluorescent cells labeled with monoclonal anti-HbF (15-3.1) and antimouse IgG, were no different (data not shown) than the percentage of F cells detected by immunoprecipitate assays with polyclonal rabbit anti-HbF antibodies.[13] The same was true when suspensions of permeabilized, fixed red cells, reacted with the same monoclonal anti-HbF and secondary antibody, were assayed by flow cytometry. As seen in Fig 1, two populations of cells with distinctive fluorescent levels were evident in flow cytometry assays. For each subject illustrated in Fig 1, the percentage of all red cells that exhibited the higher fluorescence level was indistinguishable from the percentage of F cells identified visually at the microscope.

MCH v 415 nm light absorbance of individual erythrocytes. The mean absorbance of 415 nm light for 100 untreated RBCs was identical to that of 100 fixed, permeabilized RBCs. For example, in one subject, average light absorption (±SD) for fresh RBCs was 110 ± 28 absorbance units, while that of fixed and permeabilized RBCs was 111 ± 28 units. Additions of MoAb and fluorescent secondary antibody did not affect these mean values. Such measurements verified that no hemoglobin is lost during the fixation and permeabilization procedures. Furthermore, cell morphology is maintained. For example, biconcave discs, spherocytes, and reversible and irreversible sickle forms were readily identifiable in permeabilized, fixed cells in the same proportion as in untreated cells.

To transform absorbance of 415 nm light into MCH, mean absorbance for 100 RBCs from each of a series of individuals was plotted against whole blood MCH measured in a Coulter Model S (Coulter Instruments, Hialeah, FL). As apparent in Fig 2A, there was a close correlation (r = 0.96) between mean 415 nm light absorbance by fresh RBCs suspended on glass slides and the MCH as determined by a Coulter counter. Figure 2B demonstrates that similar measurements performed on DTBP-fixed permeabilized RBCs, to which monoclonal anti-HbF and fluorescent anti-

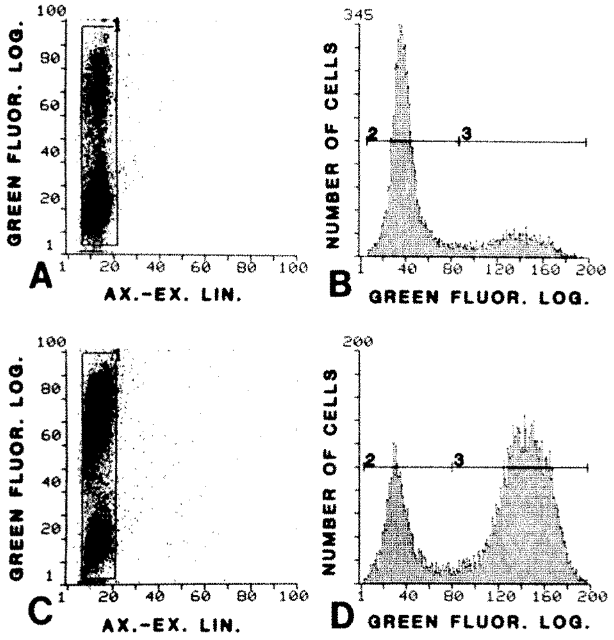

Fig 1. Flow cytometry analysis of red cells from an individual with heterocellular HPFH (panels A and B) and an individual with SS disease (panels C and D). Peripheral blood red cells were fixed, permeabilized, and then successively reacted with monoclonal anti-HbF and fluorescein-conjugated secondary antibody (see "Methods"). Panels A and C are cytograms, where the X axis equals linear-scale analysis of axial extinction of light (a measurement of cell shapes and sizes) and the Y axis equals logarithmic-scale analysis of right angle green fluorescence intensity. Reflected light from a helium-neon laser (630 nm) detects axial extinction, while an argon laser (480 nm) is used to detect right angle fluorescent emission (510 to 530 nm). Rectangular region 1 in panels A and C was defined to exclude cell doublets and encompasses erythrocytes of 4- to 10-μm diameter. Panels B and D are histograms depicting right angle green fluorescence (X axis) *v* cell number (Y axis). Panels B and D each represent 10,000 cells detected within region 1 from panels A and C, respectively. Region 2 in panels B and D demarcates a low-fluorescence non-F cell population, while region 3 demarcates a high-fluorescence F cell population. The proportion of cells in region 3 of panel B was 22.3% and in panel D was 72.1%.

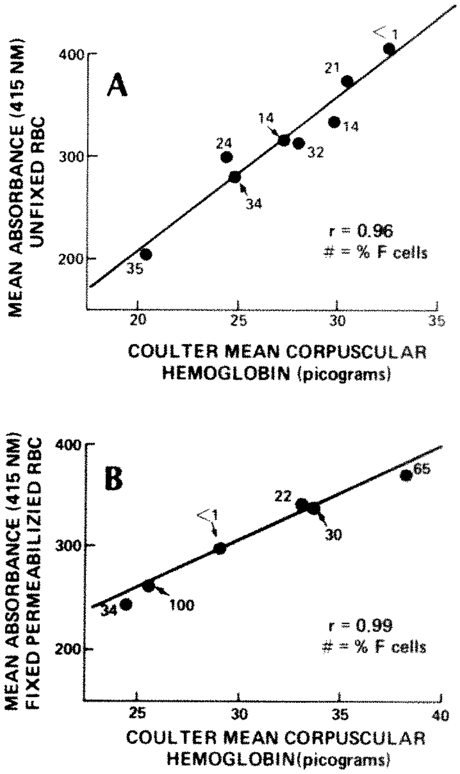

Fig 2. Mean absorbance of 415 nm light by 100 red cells compared to Coulter determined MCH for unfixed red cells (panel A) and for fixed, permeabilized red cells (panel B) reacted with anti-HbF antibody and fluorescent anti-antibody. Subjects included one pancellular HPFH (100% F cells), one heterozygote for heterocellular HPFH (21% F cells), one Fanconi's anemia (65% F cells), and two normal subjects (1% F cells); the remainder were SS subjects. Differences in slopes between panels A and B (1.5 and 0.9 respectively) are attributable to variation in light intensity and sensitivity of the photomultiplier. On any one day, however, values were reproducible.

body had been applied, leads to an equally good correlation (r = 0.99) between mean absorbance at 415 nm and the MCH as determined by Coulter assay. Thus, mean light absorbance from untreated and treated RBCs accurately reflect Coulter-derived values over a wide range of MCH and F cell levels.

MCH of F cells v non-F cells. Comparisons of the MCH measured by 415 nm absorbance of F cells *v* that of non-F cells were made in several groups of individuals. Figure 3 illustrates measurements of microscopically derived MCH in F cells *v* non-F cells for 11 individuals with SS disease. As seen, there was no difference over a wide range of MCH values between the MCH of F cells and non-F cells in any of the individuals studied ($P > 0.05$). As noted in Fig 3, three of these individuals were known to have associated alpha-thalassemia.

Five individuals with HbS-beta$^+$ thalassemia, and one with HbA-beta$^+$ thalassemia were analyzed using the same methodology (Fig 4). Figure 4 also illustrates comparisons of MCH of F cells *v* non-F cells in two normal subjects, two individuals with heterocellular HPFH with 12% and 21% F cells, and five untransfused individuals with congenital anemia, including one with Diamond-Blackfan anemia and four with Fanconi's anemia exhibiting F cell levels from 22% to 65%. In no individual was the MCH of F cells and non-F cells different ($P > 0.05$).

The degree of variability in hemoglobin content was similar for F cells and non-F cells. Among SS patients shown in Fig 3, the coefficient of variations (SD divided by mean) for hemoglobin content of F cells and non-F cells were no different (F cell: mean coefficient of variation = 20%, range 15% to 25%; non-F cells: mean coefficient of variation = 21%, range 16% to 30%). The same was true when comparisons of F cells and non-F cells were made for the heterogeneous group of individuals in Fig 4 (F cell: mean coefficient of variation = 17%, range 12% to 21%; non-F cells: mean coefficient of variation = 16%, range 12% to 25%). Furthermore, coefficients of variation were not correlated with the MCH or with F cell percentages in subjects described in either Fig 3 or Fig 4.

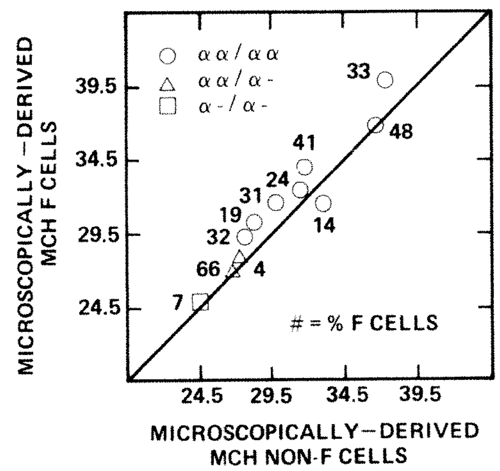

Fig 3. MCH for F cells and non-F cells in eight subjects with homozygote SS anemia and variable numbers of alpha-globin genes. F cells in these persons ranged from 7% to 48%. In this figure MCH was determined by assuming that the mean absorbance of 100 consecutive identified cells was proportional to the MCH determined by Coulter analysis. A standard line was then constructed, as in Fig 2B, and mean absorbance of 415 nm light for F cells and non-F cells was converted to MCH using this standard line. For each subject, 50 F cells were compared to 50 non-F cells regardless of the proportion of F cells present. The identification of F cells and non-F cells was made as described in "Methods."

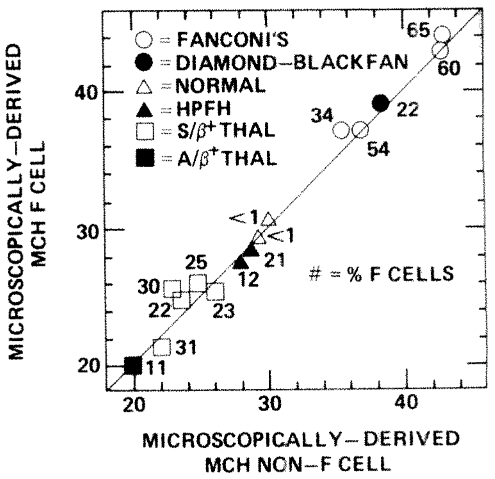

Fig 4. Comparison of the MCH of F cells and non-F cells in normals, in subjects with HbS-beta$^+$ thalassemia or HbA-beta$^+$ thalassemia, and in individuals with an elevated HbF production due to congenital anemia or heterocellular HPFH. MCH values and F cell identification were determined as outlined in "Methods" and Fig 3.

DISCUSSION

We and others have noted that in normal individuals and in individuals with hemoglobinopathies, HbF production precedes HbA production as cells mature from pronormoblast to reticulocytes.[13,14] Our previous work focused on the fact that HbF production is restricted to a subset of erythrocytes, F cells.[1,2,15] We wondered whether F cells made the same amount of HbA as non-F cells or whether early HbF production somehow restricted the amount of HbA produced in F cells. In this report we illustrate methodology that allows us to compare directly the hemoglobin content of F cells *v* non-F cells. We conclude from assays of a variety of subjects that F cells have the same MCH as non-F cells. Our data suggest that HbF and HbA production in adults are reciprocally controlled, regardless of the number of F cells produced. In addition, the fact that the MCH of F cells and non-F cells is identical suggests that the events that initiate HbF production within a red cell precursor indirectly lead to decreased HbA production in that same cell.

A reciprocal relationship between gamma- and beta-globin production can also be inferred from other studies. For example, decreased production of beta-globin and associated increases in gamma-globin are seen in some, although not all, patients with beta-thalassemia,[16,17] in individuals with pancellular (deletion) HPFH and delta-beta thalassemia,[18,19] and in two nondeletion forms of HPFH.[20,21] Heretofore, such reciprocity between gamma- and beta-globin gene production was gauged by measuring globin production in all hemoglobin-producing cells. Our data now establish that the same kind of reciprocal regulation exists within F cells from normal individuals and those with SS anemia, beta$^+$ thalassemia, or congenital anemia.

By what mechanism are HbF and HbA reciprocally controlled? Since HbF is produced earlier than HbA during erythroid development,[13,14] one might assume that the attainment of some absolute level of hemoglobin per cell would inhibit further hemoglobinization. This could result in decreased HbA production during late erythroid maturation within F cells. However, our data indicate that HbF and HbA remain reciprocally controlled over a wide range of MCH. Thus total hemoglobin content cannot, in itself, be the mediator of reciprocity between HbF and HbA production. A second possibility is that total hemoglobin production is controlled by the concentration of hemoglobin within cells, ie, MCHC. Indeed, early work by Yataganas[22] and Stohlman[23] indicate that erythroid progenitors stop dividing and hemoglobin biosynthesis falls away once a critical MCHC is attained. The importance of total hemoglobin concentration in erythropoietic development is underscored by the fact that the MCHC of eukaryotic red cells remains almost constant among evolutionarily divergent mammalian species.[24] Absolute hemoglobin content (MCH), on the other hand, is quite variable among species.[24] MCHC may therefore be the "hemostat" that curtails hemoglobin biosynthesis and may indirectly be responsible for reciprocal production of HbF and HbA. One might imagine that both F cells and non-F cells shut down hemoglobin production after some critical concentration of hemoglobin is attained. While the resulting F cells and non-F cells would have identical MCH, the early production of HbF would be later associated with a compensatory decrease in HbA.

Contrasting Patterns of DNA Strand Breakage and ADP-Ribosylation–Dependent DNA Ligation During Granulocyte and Monocyte Differentiation

By Z. Khan and G.E. Francis

Previous studies have shown that structural changes in DNA, including the ligation of pre-existing DNA breaks and the opening and closure of new breaks, occur shortly after exposure of granulomonocytic precursors (CFU-GM) to granulocyte-macrophage colony stimulating activity (GM-CSA). Monocytic differentiation of CFU-GM is selectively inhibited by compounds known to inhibit the nuclear enzyme ADP-ribosyl transferase (ADPRT). Since this enzyme, which transfers ADP-ribose units to chromatin proteins, is known to activate DNA ligase, we attempted to determine whether ligation of one or both types of DNA break is required for monocytic differentiation. Breaks in DNA were examined using the nucleoid sedimentation technique in which DNA breaks cause loss of DNA supercoiling in nucleoids and concomitant changes in their sedimentation through neutral sucrose gradients. We here report that two distinct patterns of DNA strand breakage and ligation are associated with differentiation to the granulocyte and monocyte lineages. Monocytic inducers (phorbolester and vitamin D3) predominantly produce closure of pre-existing strand breaks, whereas granulocytic inducers (granulocyte colony stimulating activity, G-CSA; retinoic acid) cause opening and closure of new breaks. Only ligation of the pre-existing breaks is highly sensitive to inhibition by 3-methoxybenzamide (a potent ADPRT inhibitor), and only monocytic differentiation is impaired by addition of this compound. These findings suggest that DNA structural changes may be directly involved in granulocyte-macrophage switching.

© 1987 by Grune & Stratton, Inc.

THE RIBOSYLATION of proteins by the nuclear enzyme ADP-ribosyl transferase (ADPRT) has been implicated as an obligatory event in differentiation in several eukaryotic cell systems.[1-4] This chromatin-bound enzyme transfers ADP-ribose units from NAD^+ to chromatin proteins forming homopolymers.[5,6] The enzyme is activated by DNA strand breakage,[7-9] and the ensuing ribosylation of chromatin proteins in turn activates DNA ligase.[10,11] It has been demonstrated that ADPRT is necessary for the repair of some types of DNA damage,[12,13] but it is not yet known whether the role of ADPRT in differentiation is linked to DNA ligation. ADP-ribosylation reactions are involved in a number of other cellular processes that might conceivably influence differentiation. Recent experiments in this laboratory[14,15] did, however, suggest that DNA ligation might be an essential step in monocytic differentiation. First, the exposure of bone marrow progenitor cells to granulocyte-macrophage colony stimulating activity (GM-CSA) is rapidly followed by an increase in ADPRT activity. Secondly, this is associated both with the closure of pre-existing DNA strand breaks and with the opening and closure of new breaks. Thirdly, the use of a variety of inhibitors of ADPRT preferentially inhibited monocytic differentiation of CFU-GM (as well as having the anticipated effect of delaying DNA ligation).

Since the early studies[14,15] had used a combined granulocyte-monocyte differentiation stimulus, the object of this study was to investigate whether inducers specific for granulocytic and monocytic differentiation behave differently with respect to the patterns of DNA strand breakage and/or ligation that follow induction to differentiation. We also wished to determine whether the monocytic differentiation induced by the pharmacologic agents phorbol myristate acetate (PMA) and vitamin D3 can, like the monocytic differentiation induced by GM-CSA, be inhibited by ADPRT inhibitors. The intention here was to establish whether agents acting by different mechanisms all require ADPRT.

MATERIALS AND METHODS

Bone marrow samples. These were obtained from healthy human volunteers with the approval of the Ethical Practices Committee of the Royal Free Hospital. Nonadherent low density bone marrow cells were prepared as previously described.[14]

Differentiation inducers. The following differentiation inducers were used: Phorbol myristate acetate (PMA) (Sigma Chemical, Poole, UK); 1,25-dihydroxyvitamin D3, all-trans retinoic acid (both gifts from Roche Products, Welwyn Garden City, UK); granulocyte-macrophage colony stimulating factors (GM-CSA) from either phytohemagglutinin-stimulated human peripheral blood leukocyte-conditioned medium (PHA-LCM) or unstimulated peripheral blood leukocytes (LCM); G-CSA from human umbilical cord conditioned medium (UCM; a gift of Dr T.C.M. Morris). PHA-LCM,[16] LCM,[14] and UCM[17] were prepared as described elsewhere and were used without further purification of the contained activities. It should be noted that although the term GM-CSA is used to refer to the activity derived from the former, we do not exclude the possibility that this material contains G-CSF, multi-CSF, and other biological activities.

Nucleoid sedimentation. The technique used was essentially that of Weniger[18] devised for the detection of low levels of DNA breaks induced by irradiation. The principle of this method is to lyse and strip cells of most of their protein in a high salt solution containing neutral detergents, which releases DNA in the form of nucleoids (highly ordered structures fixed by residues of membranes). Since the DNA in nucleoids exhibits a supercoiled structure, the presence of strand breaks increases the free rotation of DNA and therefore decreases the numbers of superhelical turns. This leads to a decrease in the sedimentation constant of the

nucleoids. The band of nucleoids is made visible by staining with the fluorescent dye ethidium bromide. The advantage of this method is that it is more sensitive than most other techniques and also avoids the detection of breaks at apurinic sites, which are induced by alkaline conditions (required for alkaline sucrose gradients and the Birnboim and Jevcak technique used in our previous study).[15]

Nonadherent low density (<1.077 g · cm^{-3}) bone marrow cells (5 × 10^5 cells/mL) were exposed to the various differentiation inducing compounds for 20 to 120 minutes in the presence and absence of 5.0 mmol/L 3-methoxybenzamide (3-MB), washed once in Dulbecco's phosphate-buffered saline (PBS) at 4°C (without 3-MB), and resuspended in PBS at 2 × 10^7 cells/mL. Cells were lysed on top of a 15% to 30% linear (10 mL) sucrose gradient containing 2 mol/L NaCl, 10 mmol/L Tris-HCl pH8, 10 mmol/L EDTA Na_2, and 30 μg/mL ethidium bromide. The gradients were overlayered with 0.4 mL of lysis mixture: 0.1 mol/L Tris, 2 mol/L NaCl, 10 mmol/L EDTA pH 8, 0.5% triton X100, and 30 μg/mL ethidium bromide. Aliquots of 100 μL of the cell suspensions (2 × 10^6 cells) were layered onto the lysis mixture and left for 15 minutes at 20°C. Gradients were centrifuged for 60 minutes in a 6 × 14 SW rotor (MSE) at 75,000 g. The cellulose nitrate tubes were then illuminated at 366 nm, and the position of the fluorescent ethidium bromide/DNA band in each tube was marked. The ratio of the sedimentation distance of the DNA of control cells (which had not been exposed to differentiation inducer) to the sedimentation distance of DNA from treated cells was used to express results.

ADP ribosyl transferase assays. ADPRT was assayed in permeabilized, low density (<1.077 g · cm^{-3}), nonadherent bone marrow cells by incorporation of [^{3}H]-NAD (kindly provided by Dr W. Wish) into acid insoluble material, essentially as previously described.[14] Cells were exposed to differentiation inducers for 30 minutes prior and for 30 minutes during the permeabilization step of the assay (by incorporating an appropriate concentration of the inducing agent in the hypotonic solution). Cells were washed in Puck's saline A (5.4 mmol/L $MgCl_2$, 137 mmol/L NaCl, 4.2 mmol/L $NaHCO_3$), then resuspended into hypotonic solution for permeabilization (9 mmol/L HEPES pH 7.8, 5 mmol/L dithiothreitol, 5.5 mmol/L glucose [wt/vol], 2% dextran of approximate mol wt 110,000, 1.0 mmol/L EDTA, 4.5 mmol/L $MgCl_2$). After approximately 90% permeabilization (as detected by trypan blue), usually 30 to 40 minutes, a ninefold volume of isotonic buffer was added giving a final concentration of 1.4 × 10^7 cells/mL. The isotonic buffer contained 40 mmol/L HEPES pH 7.8, 130 mmol/L KCl, 2.5 mmol/L dithiothreitol, 2% (wt/vol) dextran, 225 mmol/L sucrose, 2 mmol/L EDTA, and 2.3 mmol/L $MgCl_2$. Triplicate samples of 300 μL of this cell suspension were incubated at 26°C with 50 μL of 140 μmol/L [^{3}H]-NAD$^+$ (26 Ci/mmol/L) in isotonic buffer. At 10 minutes the incubation was terminated by the addition of 0.5 mL of ice-cold 10% (wt/vol) trichloracetic acid containing 5 mmol/L NAD$^+$ and 2% tetrasodium pyrophosphate. For a positive control, permeabilized cells were treated with 20 μL of 2 mg/mL bovine pancreas deoxyribonuclease I (Sigma Chemicals, Poole, UK) in 10 mmol/L Tris HCl (pH 7.8) and 5 mmol/L $MgCl_2$. In addition, trichloracetic acid was added at time zero to triplicate samples of unstimulated cells to assess nonspecific binding. After 30 minutes at 0°C, the cell precipitate was filtered onto glass fiber discs using a Skatron cell harvester. The discs were washed five times with 2% (wt/vol) trichloracetic acid containing 5 mmol/L nicotinamide and 2% (wt/vol) tetrasodium pyrophosphate. The acid insoluble material was dissolved in hyamine hydroxide and radioactivity estimated by scintillation counting.

Bone marrow cultures. Nonadherent, low density bone marrow cells were cultured for seven days in 200 μL suspension cultures in microtitre plates and assessed for differentiation induction using dual esterase staining as previously described.[19] Cells were exposed to the differentiation inducers with and without 3-MB throughout the culture period. One millimolar 3-MB was used because higher levels can be toxic and also because this is a level known to significantly inhibit monocytic differentiation in GM-CSA stimulated cultures.[14] Appropriate diluent controls were used for unstimulated cells. With the differentiation inducers, since the cells also require a growth stimulus, we used 5% PHA-LCM. This was not, of course, used in the G-CSA cultures and was replaced by 5% LCM (as a source of GM-CSA) in some cultures. After the culture period cells were harvested by cytosedimentation and were stained for nonspecific and chloroacetate esterase activity.[14]

RESULTS

Figure 1 summarizes the results of experiments in which breaks in DNA were detected by loss of DNA supercoiling in nucleoids and their subsequent changes in sedimentation

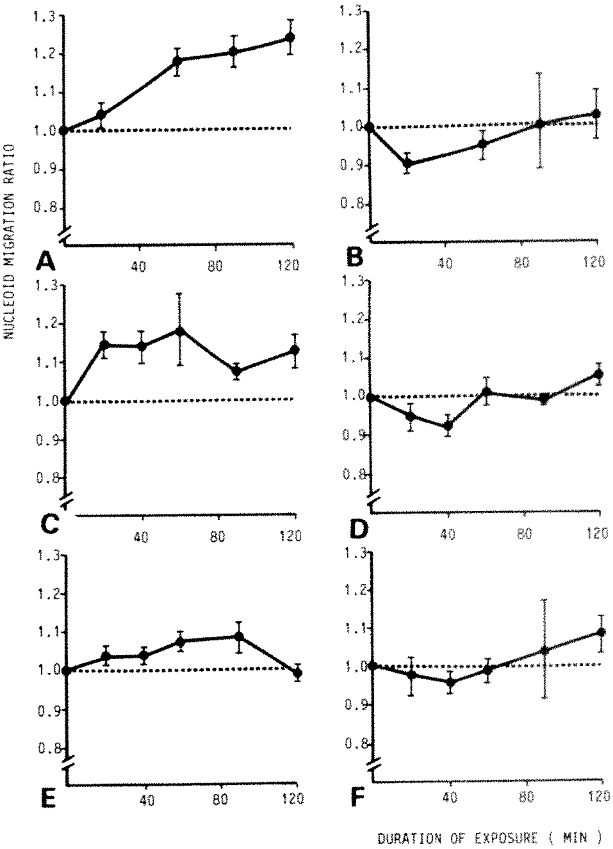

Fig 1. Migration ratios on nucleoid sedimentation gradients following treatment with physiologic and pharmacologic differentiation inducers. (A) GM-CSA (5% PHA-LCM or 5% LCM); (B) GM-CSA + 5.0 mmol/L 3-methoxybenzamide; (C) 10^{-9} mol/L PMA; (D) 10^{-6} mol/L retinoic acid; (E) 10^{-9} mol/L 1-25,dihydroxy vitamin D3; (F) G-CSA (50% umbilical cord-conditioned medium). Results are mean of four, four, five, six, five and two independent experiments for A through F respectively. With monocytic inducers (PMA and Vitamin D3) the increase in migration ratio indicates the closure of pre-existing strand breaks. With the granulocytic differentiation inducers (retinoic acid and G-CSA) there is opening of new strand breaks that are closed within 50 to 90 minutes of exposure. With a source of GM-CSA (PHA-LCM), closure of pre-existing strand breaks predominates in the absence of ADPRT inhibitor (3-MB), but in its presence there is opening and closure of new breaks similar to that seen with the granulocytic inducers.

through neutral sucrose gradients. Differences in sedimentation rate were expressed as a migration ratio relating the distance migrated by the test preparation to the distance migrated by nucleoids from the untreated control. Migration ratios >1 and <1 indicate DNA with less and more breaks respectively than present in the control preparation. As in previous experiments using a different technique, the exposure of cells to GM-CSA (obtained from two different sources, PHA-LCM and LCM) produced dual effects (Figs 1A and 1B): first, the closure of pre-existing strand breaks; secondly, in the presence of 5.0 mmol/L 3-methoxybenzamide, a potent inhibitor of ADPRT, there was also evidence of the opening and subsequent closure of new breaks. Unstimulated cells do not (as demonstrated in earlier studies) show such DNA breaks when exposed to 3-MB.

We next looked at the effects of two known inducers of monocytic differentiation (PMA and vitamin D3) and two inducers of granulocytic differentiation (retinoic acid and G-CSA). The results in Figs 1C through 1F show two distinct patterns of DNA strand breakage and ligation. The monocytic inducers predominantly show closure of pre-existing strand breaks, and the granulocytic inducers show opening of new strand breaks followed (within 50 to 90 minutes of exposure) by their ligation.

To assess whether both types of break require ADP-ribosyl transferase for their ligation, cells were exposed to both granulocytic and monocytic inducers of differentiation in the presence of 3-methoxybenzamide. Figure 2, panels A and C, shows that this agent effectively prevents the closure of pre-existing strand breaks. In addition, the nucleoid sedimentation profiles with PMA and vitamin D3 in the presence of 3-MB indicate that new strand breaks are also opening. These breaks are not seen without 3-MB because their effect on the nucleoid profile is masked by the closure of pre-existing strand breaks, this being the predominant effect. In contrast to inhibition of ligation of pre-existing breaks, some ligation of new breaks was evident (as an upward trend) in four of five profiles with 5 mmol/L 3-MB (Fig 1B and Fig 2A, B and D).

DNA breaks are known to activate the enzyme ADP-ribosyl transferase. Despite the different nucleoid sedimentation profiles, there was no gross difference (Fig 3) between the four different compounds with respect to the level of activation of ADPRT. Nor was there any difference between the two groups of compounds with respect to the kinetics of activation of ADPRT. Assays at an earlier time point (10 minutes) than that of Fig 3 also failed to show differences between the two groups (data not shown). In all cases, as one might expect, this was much lower than the activation produced by DNA damage (eg, nuclease-induced DNA strand breakages).

Contrasting effects of ADPRT inhibitor 3-methoxybenzamide on granulocytic and monocytic differentiation induced by the four compounds are shown in Fig 4. To avoid toxicity (since agents were incorporated throughout the culture period), lower concentrations of both the inducers and the ADPRT inhibitor were used than in other experiments. As in previous studies with GM-CSA, monocytic differentiation was inhibited, whereas granulocytic differentiation was spared or even enhanced. Thus the pharmacologic inducers behave in a similar way to GM-CSA.

DISCUSSION

The results of nucleoid sedimentation experiments confirmed our earlier finding[15] (using a fluorometric method[20] to

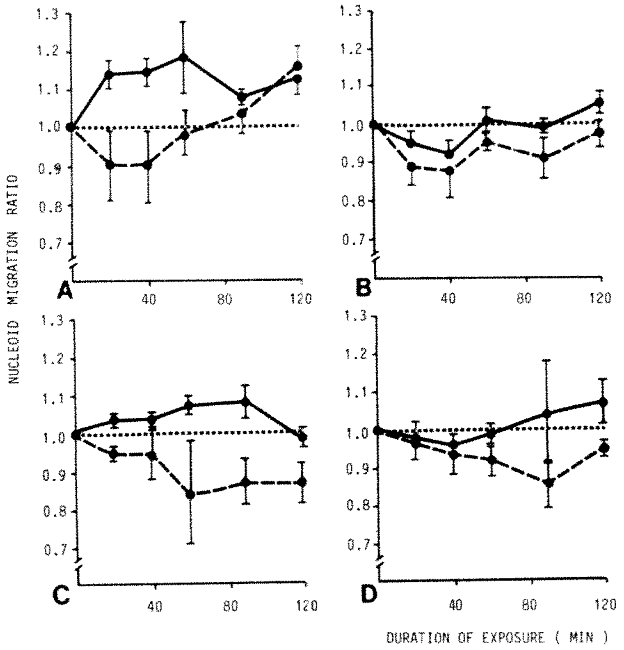

Fig 2. The effect of ADPRT inhibitor (5.0 mmol/L 3-methoxybenzamide) on nucleoid sedimentation after exposure to differentiation inducers. Dashed and solid lines show migration ratios with and without inhibitor respectively. Differentiation inducers are (A) 10^{-9} mol/L PMA; (B) 10^{-6} mol/L retinoic acid; (C) 10^{-9} mol/L 1-25,dihydroxy vitamin D3; (D) G-CSA (50% umbilical cord-conditioned medium).

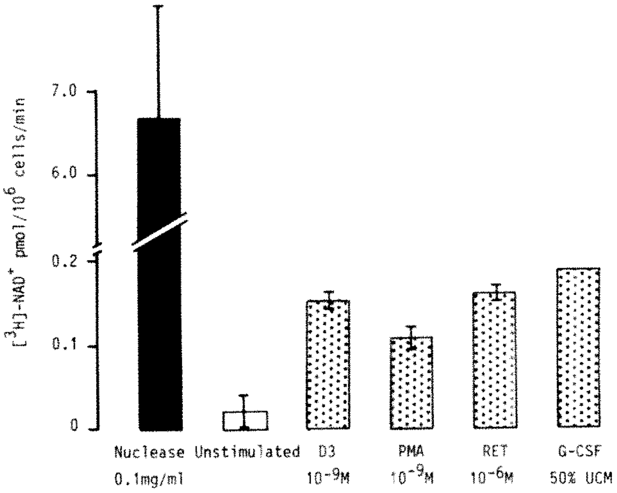

Fig 3. ADPRT activity levels (±SEM) after treatment with differentiation inducers for one hour (30 minutes before and 30 minutes during the cell permeabilization step) and with bovine pancreatic nuclease (positive control). 3-methoxybenzamide 2.5 mmol/L abolished all activity with each of the inducers (data not shown).

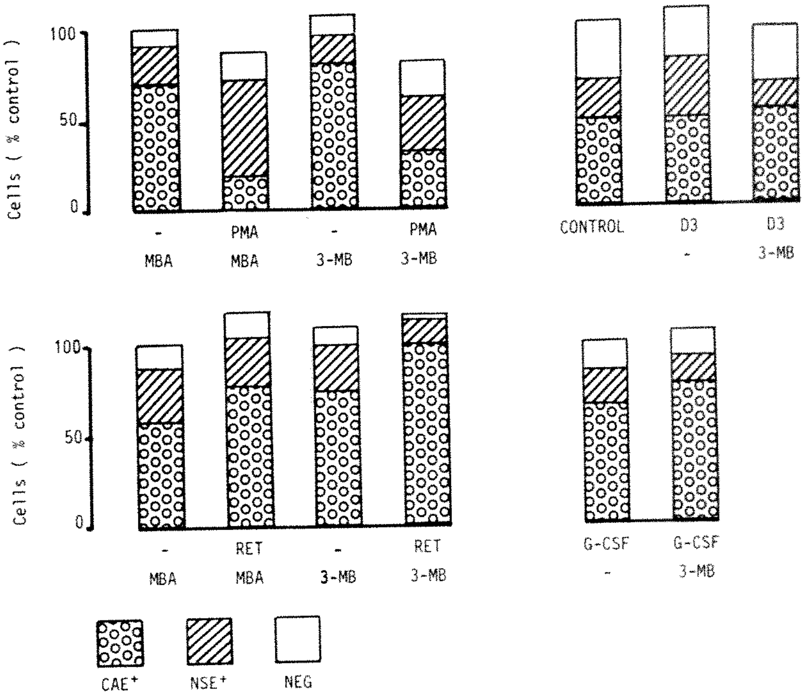

Fig 4. Effect of ADPRT inhibitor (1 mmol/L 3-methoxy-benzamide, 3-MB) on differentiation induction. The structural analogue 3-methoxybenzoic acid (1 mmol/L MBA), which is not significantly inhibitory for ADPRT, was used as a control. PMA 3 × 10^{-10} mol/L; Retinoic acid (RET) 10^{-7} mol/L; vitamin D3 10^{-9} mol/L; G-CSA 10% UCM. Cells were typed by dual esterase staining into:chloroacetate esterase positive cells (CAE$^+$ granulocytes); nonspecific esterase positive cells (NSE$^+$ monocytes); and negative cells (NEG). Results are representative examples of three experiments for each agent. Other doses of the same agents were also tested (data not shown). Inhibition of ADPRT by 3-MB reduced the monocytic differentiation in these cultures but not the granulocytic.

assess DNA strand breakage) that stimulation of bone marrow cells by GM-CSA is associated both with the closure of pre-existing strand breaks and with the opening of new breaks. To demonstrate the latter, the cells have to be exposed to an inhibitor of the nuclear enzyme ADP-ribosyl transferase, which inhibits the closure of pre-existing strand breaks (the predominant effect in GM-CSA stimulated cultures). The inhibitors of ADPRT not only affect the closure of DNA strand breaks induced by GM-CSA[15] but have an effect on the differentiation potential of the cells so treated.[14] Both in this and earlier studies, GM-CSA-stimulated bone marrow cells exposed to a range of ADPRT inhibitors show selective inhibition of monocytic differentiation while retaining the ability to differentiate to the granulocytic lineage.[14] Although the evidence for involvement of ADPRT in monocytic differentiation is indirect, no known property of the inhibitory compounds, other than their relative capacities to inhibit ADPRT, correlates closely with their capacity to inhibit monocyte formation.

Analysis of the response to agents that selectively promote either granulocytic or monocytic differentiation revealed two distinct patterns, with monocytic differentiation being associated predominantly with closure of pre-existing strand breaks and granulocytic differentiation being associated with the opening of new breaks. The shift in the pattern of nucleoid sedimentation seen when GM-CSA is used in the presence and absence of 5.0 mmol/L 3-methoxybenzamide not only mimics the two different nucleoid sedimentation patterns seen with monocyte and granulocyte inducers respectively but also produces a shift in the differentiation pattern observed. It therefore seems likely that the DNA structural changes reflected by the different patterns in the nucleoid sedimentation may well be directly involved in granulocyte-macrophage switching.

The changes in DNA supercoiling observed with G-CSA and vitamin D3 (Figs 1C and F) were less pronounced than for retinoic acid and PMA respectively (Figs 1C and D), and this could reflect differences in the intensity of the differentiation stimulus. The only divergence in pattern observed was the decline in migration ratio at 120 minutes with vitamin D3 not observed with PMA. Such a change could be due to cell damage by the agent.

The experiments shown in Fig 2 investigated the effect of ADPRT inhibitor (5 mmol/L 3-MB), added with the four differentiation inducers, on nucleoid sedimentation. With all four inducers there were shifted nucleoid profiles, indicating that the ligation of some, but not necessarily all, DNA breaks is dependent on ADPRT. In addition, the experiments with ADPRT inhibitor revealed that all five compounds (GM-CSA in Fig 1B; PMA, RET, D3, G-CSA in Fig 2A through D, dashed lines) induced the net opening of new strand breaks. This was not seen with the monocyte inducers and GM-CSA without 3-MB because it was masked by closure of pre-existing strand breaks causing a net increase in migration ratio. Since in four of five profiles with 3-MB there is an upward trend after the nadir in migration ratio, this suggests that at least some ligation occurs at 5 mmol/L 3-MB (twice the concentration required to inhibit all detectable enzyme activity after one hour of incubation). Whether this upward trend is due to the ligation of the new breaks just formed or to a shift in the balance between opening of new and ligation of pre-existing breaks cannot be established from these profiles. One can conclude, however, that ligation of new breaks (or of a subset of pre-existing breaks) is either ADPRT independent or much less sensitive to inhibition of 3-MB than the ligation of all or most pre-existing DNA breaks.

The findings in marrow cultures (Fig 4) suggest a simple interpretation of these results. 3-MB, even at 1 mmol/L, significantly inhibits monocytic differentiation induced either by PMA (3 × 10^{-10} – 3 × 10^{-9} mol/L) or by vitamin

D3 (10^{-9} mol/L); it also inhibits the residual monocytic differentiation in RET (10^{-7} – 10^{-6} mol/L) and G-CSA-stimulated cultures. In contrast, granulocytic differentiation was not inhibited but was even enhanced by 3-MB. Taken together, the nucleoid and culture findings suggest that monocytic differentiation is associated with and dependent on ADPRT-dependent ligation of pre-existing breaks. All the five inducers also cause the opening of new breaks, and since ADPRT inhibitors only significantly affect monocytic differentiation, one has to conclude that either (1) the ligation of new breaks (if it occurs) is not ADPRT mediated, or (2) in time it escapes the competitive inhibition of 3-MB, or (3) ligation is ADPRT mediated, but is not an essential step in differentiation to either lineage. On balance, in view of the nucleoid profiles obtained with 5 mmol/L 3-MB, we favor the first hypothesis.

The new breaks seem unlikely to be due to DNA damage. Sham-treated, unstimulated cells do not acquire breaks over this time scale.[15] Also, a consistent degree of damage is unlikely with five dissimilar agents. All the agents, including the pharmacologic inducers, directly or indirectly stimulate cell growth[21-23] prior to terminal differentiation. Although DNA synthesis does directly involve DNA strand breakage, this is unlikely to be the cause of the breaks seen here because of the rapidity with which they occur. The demonstration in recent studies that the DNA breaks induced by retinoic acid are protein associated (Francis, Berney, Khan, and North, unpublished) raises the possibility that DNA topoisomerases might cause the transient new DNA breaks and relaxation of supercoiling observed here. This might explain a DNA ligation step refractory to ADPRT inhibitors. Signal transduction in the epidermal growth factor system seems to involve DNA topoisomerase.[24-26] Involvement of DNA topoisomerases in the regulation of eukaryocyte gene expression is also suggested in other systems.[27]

Since ADPRT activity is increased by DNA strand breakage, enzyme assays were performed to determine whether the enzyme activity was higher with one or other types of inducer. The observation that the levels of enzyme activation are similar with the four compounds suggests that differences in enzyme activity are not responsible for the differences observed in behavior of nucleoids. In this and in our previous studies,[14,15] unstimulated cells (ie, cells that had neither been exposed to GM-CSA nor to a differentiation inducer) had very low levels of ADPRT activity. This suggests that the pre-existing breaks that close with monocytic differentiation are present in some form that does not activate the enzyme.

Why should the granulocytic inducers activate ADPRT if the breaks induced do not appear to require ADP-ribosylation for ligation? Ferro and Olivera[28] have suggested that ADP ribosylation may be important in regulation of DNA topoisomerase activity, specifically in the prevention of inappropriate ligation (eg, sister chromatid exchanges). If, as we suspect, DNA topoisomerases are responsible for the new DNA breaks, concomitant activation of ADPRT might also have a role in that reaction distinct from its apparent role in regulation of DNA ligation in monocytic differentiation.

This study contributes to the increasing body of evidence that DNA strand breakage and ADP-ribosyl transferase-mediated DNA ligation is involved in eukaryotic cell differentiation.[1-4,29-38] It is, as far as we are aware, the first report in which differentiation to two distinct but related cell lineages has shown different behavior with respect to DNA strand breakage and ligation. The present study indicates that in addition to a generalized involvement in differentiation, ADP-ribosylation may be specifically associated with lineage switch mechanisms, whereby pluripotent progenitor cells give rise to several lineages of differentiated progeny.

Stromal Growth Factor Production in Irradiated Lectin Exposed Long-Term Murine Bone Marrow Cultures

By Thomas A. Alberico, James N. Ihle, Chi-Ming Liang, Helen E. McGrath, and Peter J. Quesenberry

Hematopoietic regulatory factors produced by adherent (stromal) cells in long-term murine bone marrow cultures have been investigated. Using an in situ double layer agar overlay system, we demonstrated that exposure of the stromal cells to 1,100-rad irradiation increased their activities in stimulating colony formation of FDC-P1, an interleukin 3 (IL 3)-responsive cell line. The colony-stimulating activities (CSAs) of the irradiated stroma also stimulated normal marrow cells to form granulocyte-macrophage, megakaryocyte, and mixed lineage colonies. Addition of the lectin pokeweed mitogen to the irradiated stroma increased the level of CSAs. The FDC-P1 CSA of the irradiated stroma was inhibited by antibodies directed against murine granulocyte-macrophage colony stimulating factor (GM-CSF) but not by those against murine IL 3. Stromal-derived CSA for marrow cells was also partially blocked by anti-GM-CSF antibodies, probably reflecting the presence of other CSAs such as CSF-1. This latter growth factor has been found to be present in conditioned media from Dexter stroma, but levels are not increased after irradiation or lectin exposure. Partially purified GM-CSF, like IL 3, stimulated FDC-P1 proliferation and granulocyte, macrophage, and megakaryocyte colony formation. These results indicate that the major terminal differentiating hormone elicited by irradiation or lectin exposure of murine marrow stromal cells is GM-CSF. This growth factor, along with CSF-1, can account for the differentiated progeny produced in this system: macrophages, granulocytes, and megakaryocytes.

COLONY-stimulating activities (CSAs) are important for the proliferation of hematopoietic stem cells in in vitro clonogenic cultures.[1-3] Cytokines such as erythropoietin, granulocyte-macrophage colony stimulating factor (GM-CSF), interleukin 3 (IL 3), granulocyte CSF (G-CSF), and macrophage CSF (CSF-1) are known to have stimulating activities on their target cells.[4-10] Recently these cytokines have been purified, and recombinant DNA-derived proteins have been produced from bacteria and mammalian cells.[4-15] The functions and regulation of these cytokines in hematopoietic systems, however, have not been thoroughly evaluated.

Using a long-term murine bone marrow culture, Dexter and Lajtha[16] and Dexter et al[17] have developed a system that provides a useful in vitro model for exploring hematopoietic regulation. The Dexter system, which simulates the bone marrow microenvironment, is composed of a complex adherent layer formed by both hematopoietic cells and adherent nonhematopoietic (stromal) cells. Although this culture system supports prolonged production of granulocytes, megakaryocytes, and macrophages, early studies of the conditioned medium had shown little or only transiently detectable amounts of CSAs.[18] Using a double layer agar overlay system, Heard et al[19] improved the sensitivity of the assays and successfully demonstrated elaboration of CSA from the adherent cell population of long-term murine cultures. Subsequently, Gualtieri et al[20] have shown that after in vitro radiation of Dexter culture, CSAs are markedly increased. The elicited CSAs, however, have not yet been identified and characterized.

In this paper we reported that treatment with lectin pokeweed mitogen further increased the CSAs' elaboration by irradiated adherent stromal cells. The secreted CSAs were identified by using antibodies directed against known cytokines.

MATERIALS AND METHODS

Long-term bone marrow cultures. Long-term liquid murine bone marrow cultures were established as previously described.[21] Bone marrow obtained from the tibias and femurs of either ICR or BDF1 12- to 20-week-old female mice (Dominion Labs, Dublin, VA and Jackson Labs, Bar Harbor, ME, respectively) were used. Cultures were established in 25 cm^2 Corning tissue culture flasks either from single cell suspensions or by expelling the marrow from one tibia and one femur directly onto the flask. Alternatively, cultures were carried out in 35 mm^2 Corning tissue culture plates or 0.32 cm^2 96-well Costar flat bottom tissue culture microtiter wells from single cell suspensions. In all experiments, although variable volumes of Fishers's media, 20% horse serum, and 10^{-7} mol/L hydrocortisone were used, cell concentrations were established between 3 to 4 × 10^6 cells per cc. Cultures were incubated at 33°C with 5% CO_2. They were maintained with weekly demidepopulation and replenished with cell-free fresh media.

In vitro irradiation. After three weeks of growth (one experiment was carried out to four weeks), nonadherent cells were removed, and all cultures were totally depopulated. The stromal layer was then exposed to 1,100 rad, using a gamma-cell 40 cesium 137 irradiation unit (Atomic Energy of Canada Limited, Ottawa, Canada) at a rate of 123 to 126 rad per minute. Control unirradiated stromal layers were included in each experiment. In one series of experiments, stromal layers were exposed to varying levels of irradiation (250, 700, 900, 1,100, 1,500, and 2,000 rad). After exposing these cultures to irradiation, they were incubated another seven days at 33°C with 5% CO_2 and 95% humidity. After seven days of incubation postirradiation, all supernatant media was removed and the stroma was assessed directly for CSA. Alternatively (see below), condition media was harvested from these cultures and assessed for CSA levels.

Stromal assay for colony-stimulating activity. Stroma was assayed for CSA using the method described by Heard et al[19] and modified by Gualtieri et al.[20] Seven days postirradiation all supernatant media was removed from these cultures, and a double-layer

agar system was employed to assay for CSA. Briefly, an underlayer of McCoy's 5A media with 2 mmol/L l-glutamine, 16 μg/mL L-asparagine, 8 μg/mL L-serine, 1 mmol/L sodium pyruvate, 1 × 10^{-4} mercaptoethanol, and 15% fetal calf serum, mixed in equal part with 1% agar, was added to these cultures (after all supernatant had been removed) and allowed to gel for 20 to 30 minutes. This layer separated the adherent stromal cells from the target cell population. In a number of these experiments, including variable-dose radiation experiments, potential stimulatory effect of pokeweed mitogen (GIBCO, Grand Island, NY) was examined by adding this lectin at a final concentration of 2.5 μg/mL to the underlayer of both irradiated and nonirradiated cultures. After allowing this underlayer to gel, an overlayer was then added containing McCoy's media with additives plus 0.3% agar, along with the target cell population. The target cell populations were either the IL 3-dependent cell line, FDC-P1,[22] or ICR or BDF1 murine marrow cells at a concentration of 0.5 to 1 × 10^5 cells/mL. Cultures were incubated for seven days at 37°C and 5% CO_2. After incubation all cultures were removed from the incubator, fixed with formalin, and, by using a dissecting microscope, colonies of 50 cells or greater were scored.

Bioassays of conditioned media. In experiments where the conditioned media was used to measure the CSA produced by the stromal cells, Dexter cultures were established and irradiated as described above. The adherent layers were then incubated in media with or without 2.5 μg/mL pokeweed mitogen for 24, 48, 96, 120, 168 hours. At these time points the conditioned media was collected and used as a stimulus in a single layer version of the agar culture system described above. Unconcentrated conditioned medium was added at various levels to stimulate both FDC-P1 and fresh murine marrow colony formation in the agar cultures. Media from Dexter flasks with no cells and with and without pokeweed mitogen at a concentration of 2.5 μg/mL served as controls.

Colony morphology. Colonies are classified as macrophage, granulocyte, macrophage/granulocyte, macrophage/monocyte (see legend for Table 1) and megakaryocyte. Soft-agar cultures were fixed in 10% formalin seven days after plating, and whole-agar slide preparations were then made from these cultures.[20] These slides were then stained for acetylcholinesterase and counterstained with hematoxylin. Megakaryocyte colonies were defined as aggregates of three or more acetylcholinesterase-positive cells, and mixed colonies were defined as colonies that had <90% of the predominant cell type. Degenerate colonies were scored when distinctive morphological features were absent.

Antibody blocking experiments with adherent feeder layer. Dexter cultures were established and maintained in Costar 96-well microtiter tissue culture plates, as described above, to carry out experiments that involved limited amounts of reagents (ie, antibody to IL 3). Initial concentrations in the Costar 96-well microtiter plates were 3 to 4 × 10^6 cells/mL with a volume of 0.3 mL per well. All wells were demidepopulated weekly with total depopulation and replacement with cell-free media at three weeks and exposure of the adherent layers to 1,100 rad. Underlayers and overlayers contained the same concentration of McCoy's media and agar as described above. A total of 0.22 mL was used in each well, with 0.12 mL in the underlayers and 0.1 mL in the overlayer. Additives were plated in the underlayer or added directly to the overlayer. Additives included pokeweed mitogen at a concentration of 2.5 μg/mL, antibody to IL 3 at 1 mg/mL, and/or control rabbit IgG at 1 mg/mL. Antibody to IL 3 and control rabbit immunoglobulin was prepared as described by Bowlin et al.[23] Antibody to IL 3 at a concentration of 1 mg/mL totally inhibited FDC-P1 incorporation of tritiated thymidine, whereas control rabbit IgG at the same concentration showed no inhibition.

Antibody blocking of CM. In experiments assessing anti-IL 3 antibody blocking of conditioned media (cm), target cell populations were cultured in 96-well microtiter or Terasake plates using the agar system previously described. These target cells included the IL 3-dependent cell line FDC-P1 or normal murine marrow cells. Similar experiments utilizing stromal-derived cm were carried out using antibodies to recombinant GM-CSF (see below).

Polyclonal antibodies against recombinant Escherichia coli-*derived murine GM-CSF.* Purified recombinant murine GM-CSF (200 μg/rabbit) in an emulsion formed by equal volume of normal saline and Freund's complete adjuvant was injected into New Zealand white rabbits (2 mL/rabbit) at multiple sites intradermally. The rabbit was boosted with the same amount of antigen in Freund's incomplete adjuvant twice at one-month intervals. Serum was obtained ten to 14 days after each boost. The anti-GM-CSF serum was partially purified by precipitation with 40% ammonium sulfate, followed by dialysis against phosphate-buffered saline (PBS), pH 7.2. The solution was then incubated at 56°C to inactivate complement. The preparation from 1 mL of rabbit serum generally yielded 10 to 15 mg of rabbit IgGs. These anti-GM-CSF antibodies neutralized the cell proliferative activity of recombinant murine GM-CSF while pre-immune serum showed no effect.

Assay of natural murine GM-CSF (GM-CSA-2) or recombinant GM-CSF for FDC-P1 colony-stimulating activity. GM-CSA-2 was partially purified from supernatants of concanavalin A (Con A)-activated splenic T lymphocytes.[23] Briefly, this involved removing BALB/c spleens, gently mashing them, and washing these cells in RPMI 1640. This suspension was cleansed of RBCs and was cultured with 5 μg/mL of Con A for 48 hours at 37°C. Cells were removed by centrifugation, and the supernatant was used for purification. The purification of the supernatant included ammonium sulfate precipitation with subsequent dialysis against a phosphate buffer. This dialysate was clarified by centrifugation at 10,000 RPM for 30 minutes and then applied to a diethyl aminoethyl (DEAE) cellulose column. The GM-CSA-2 activity was eluted from the column at 0.1 mol/L NaCl.[23] This GM-CSA-2 purified in this manner is serologically and biochemically distinct from IL 3 and is not inhibited by antibody to IL 3.[23] One unit of activity is defined as the amount of GM-CSA-2 that in 1 mL gives 50% maximal stimulation of a GM-CSA-responsive cell population. In a single-layer soft-agar system consisting of McCoy's 5A media plus additives and 0.3% agar (at a concentration of 80 U/mL), GM-CSA-2 was assayed for FDC-P1 CSA. These cultures were incubated for seven days at 37°C, 5% CO_2. After seven days they were removed from the incubator, fixed with formalin, and colonies of 50 cells or greater were scored. Alternatively, recombinant *E coli*-derived murine GM-CSF was tested.[24]

Sources of IL 3. IL 3 was purified to homogeneity from WEHI-3-conditioned media, as previously described.[10] Briefly, conditioned media from WEHI-3 murine myelomonocytic leukemia cells was concentrated on a 10,000-mol wt Amicon membrane. Ammonium sulfate fractionation was then used with a 50% to 80% fraction chromatographed on DEAE cellulose. IL 3, unlike GM-CSF, was not bound to the resin and was collected in the flow-through fraction. The flow-through fraction was concentrated and further purified by hydroxyl appatite column chromatography, followed by G70 Sephadex and high-pressure liquid chromatography.[10,25] The IL 3 preparations were then diluted in RPMI 1640 with 10% fetal calf serum and assayed for IL 3 using thymidine incorporation into the FDC-P1 indicator cell line, as previously described.[26] The preparation of IL 3 contained 0.2 ng/U of activity, with one unit of activity defined as the amount of IL 3 that in 1 mL gives 50% of maximal tritiated thymidine incorporation into FDC-P1 cells in culture.

Histochemical stains of stroma. Histochemical stains were used to evaluate the cytochemistry of the stromal cell population following XRT and pokeweed mitogen exposure. These included alpha naphthyl acetate (nonspecific) esterase, acid phosphatase, and alkaline phosphatase. Stromal cells were stained 48 hours after exposure to XRT and pokeweed mitogen. Over 500 cells were counted per 35-mm plate, and percent positivity was scored qualitatively 0 to 4+. Cells in the 2 to 4+ range were scored as positives.

RESULTS

In situ stromal assay for growth factor production. The capacity of nonirradiated and irradiated 3- to 4-week-old Dexter stroma to produce a growth factor capable of stimulating proliferation of FDC-P1 cells is shown in Fig 1. Total colonies of 50 cells or greater were scored at seven days. There was an 18.2-fold increase in the numbers of FDC-P1 colonies stimulated by the irradiated stroma as compared to the nonirradiated stroma. However, colony growth in this system did not approach that seen with IL 3-rich WEHI-3-conditioned media; in these preparations FDC-P1 colonies were too numerous to count. Pokeweed mitogen (PWM) stimulates IL 3 production from T lymphocytes. Thus we added this to the adherent Dexter cell underlayer to evaluate its effect on the irradiated and nonirradiated stromal growth factor production (Fig 2). Addition of pokeweed mitogen at a concentration of 2.5 μg/mL to nonirradiated stroma did not increase colony formation of the FDC-P1 cell line in the agar overlayers as compared to nonirradiated stroma without pokeweed mitogen. However, when the pokeweed mitogen was added to the underlayer of cultures with irradiated stroma, we found an 11.4-fold increase in colony numbers as compared to irradiated stroma without pokeweed mitogen. Different levels of irradiation were also assessed with and without the addition of PWM. As before, there is a marked increase in FDC-P1 CSA with the addition of PWM, with activity reaching a plateau at 700 rad (Fig 3). Although detectable, FDC-P1 CSA is lower without the addition of PWM, and there is a similar increase in FDC-P1 CSA with

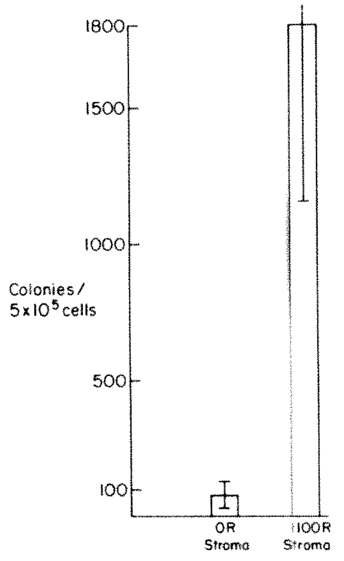

Fig 1. In situ stromal assay for FDC-P1 CSA from irradiated and nonirradiated adherent cells in Dexter culture. Adherent stromal layers from 3- to 4-week-old Dexter stroma were overlaid with 0.5% agar and McCoy's media, followed by a second overlayer consisting of 0.3% agar and media and the FDC-P1 target cell population (see Materials and Methods). CSA levels are expressed as the mean number of FDC-P1 colonies per 5 × 10^5 target cells ±1 SEM. These data are pooled from seven experiments. Two to four flasks or petri dishes were scored per group in each experiment. Abbreviations: OR = no irradiation; 1100R = 1,100 rad.

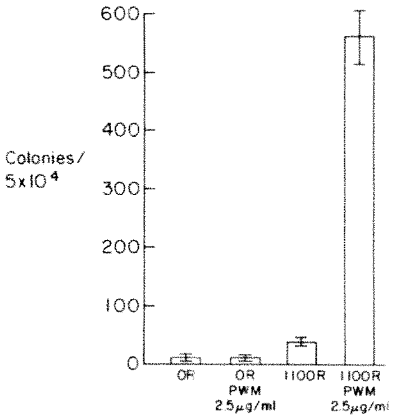

Fig 2. In situ stromal assay for FDC-P1 CSA from irradiated and nonirradiated adherent cells in Dexter culture after exposure to pokeweed mitogen (PWM). These experiments were carried out as described in the legend for Fig 1, except for the addition of 2.5 μg PWM to the 0 and 1,100-rad groups (see Materials and Methods). The FDC-P1 cells were plated at 5 × 10^4 in these experiments, as opposed to 5 × 10^5 in the experiments presented in Fig 1. CSA levels are expressed by mean numbers of FDC-P1 colonies/5 × 10^4 target cells ± 1 SEM. These data were pooled from three experiments, with three to four flasks or petri dishes scored per group in each experiment. Abbreviations: OR = no radiation; OR PWM = no radiation with pokeweed mitogen; 1100R = 1,100 rad; 1100R PWM = 1,100 rad with pokeweed mitogen.

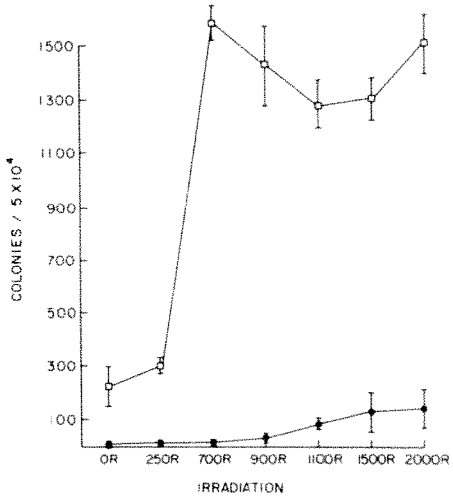

Fig 3. In situ assay for FDC-P1 CSA from Dexter culture adherent cells after exposure to varying irradiation levels with and without the addition of pokeweed mitogen (2.5 μg/mL). Abscissa represents escalating doses of radiation to which the adherent cells were exposed. This experiment was performed in a manner identical to that described in Fig 2, except for the varying levels of radiation. CSA levels are expressed as mean number of FDC-P1 colonies/5 × 10^4 target cells ± 1 SEM. This graph represents one of two experiments that were qualitatively similar. Three to four petri dishes were scored per group in each experiment. □, Irradiation + PWM; ●, irradiation alone.

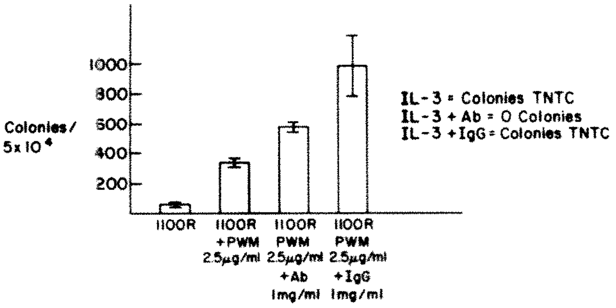

Fig 4. In situ stromal assay evaluating the effect of anti-IL 3 antibodies on FDC-P1 CSAs generated from irradiated pokeweed mitogen stroma. Antibody to IL 3 was prepared by rabbit innoculation as described by Bowlin et al.[23] Antibody (Ab) and control IgG were plated at a dose of 1 mg/mL along with pokeweed mitogen at a concentration of 2.5 µg/mL in the underlayer. Target cell population was the FDC-P1 cell line. Cultures were established in microtiter wells; these data represent two experiments, with four to six microtiter wells scored per group in each experiment. CSA levels are expressed by mean numbers of FDC-P1 colonies $\times 10^4$ target cells ±1 SEM. TNTC refer to cultures in which colonies were too numerous to count. Legend in left upper quadrant of figure indicates that IL 3 at a concentration of 4 ng/mL stimulated FDC-P1 colonies that were TNTC. Ab at 1 mg/mL totally blocked IL 3-stimulated FDC-P1 colony formation, whereas control rabbit IgG (1 mg/mL) did not inhibit colony formation.

irradiation alone, which plateaus at 1500 rad. These data suggested that the FDC-P1-stimulating activity from lectin-stimulated irradiated stroma might be IL 3. However, an antibody to IL 3 that effectively blocked pure IL 3 stimulation of clonal growth of FDC-P1 cells in a double-layer agar system did not block irradiated PWM stromal-induced colony formation; in fact, both the IgG control and anti-IL 3 antibody increased colony formation (Fig 4).

Assays of conditioned media. As stated previously, we (and others) have had difficulty in detecting significant levels of myeloid growth factors from Dexter culture conditioned media. We also have had repeatedly negative results when conditioned media was assayed for IL 3 using tritiated thymidine incorporation into the FDC-P1 line. It was for this reason that the in situ assay method was used. However, since high levels of activity were seen when the irradiated stroma was exposed to PWM, we again evaluated media conditioned by the irradiated lectin-induced stromal cells. Figure 5 demonstrates high levels of CSA in this conditioned media, stimulating clonal proliferation of both FDC-P1 and fresh murine BDF1 marrow cells. There was no stimulation of the FDC-P1 cell line by media conditioned by irradiated stroma without pokeweed mitogen, but cm from irradiated stroma exposed to pokeweed mitogen had increased levels of CSF for both marrow and FDC-P1 cells. However, the threshold for stimulation was lower for the murine-marrow target cell population compared to the FDC-P1 target cells. Figure 5 shows the effect of the conditioned media after 48 hours of culture. These results were confirmed in two other experiments, and the same phenomenon was noted at time points of 24 and 168 hours in one of these three experiments.

We have previously shown that CSF-1, as determined by radioimmunoassay, was present in cm from Dexter cultures and that the levels were not increased with irradiation.[20] We have repeated these studies here with similar results and have also shown that CSF-1 levels from irradiated or nonirradiated stroma were not increased by exposure to pokeweed mitogen (data not shown). In addition, we have cultured FDC-P1 cells with pure CSF-1 (courtesy of Dr Abdul Waheed and Dr Richard Shadduck) over a range of 78 to 10,000 U/mL and have shown that CSF-1 does not stimulate any clonal proliferation of these cells in soft agar culture.

Colony morphology. Table 1 shows types of murine marrow colonies observed in assays of conditioned media. The conditioned media obtained from irradiated lectin-treated stromal cells increased the numbers of all types of colonies, with up to a 70-fold increase in granulocyte-colony formation.

Assay of GM-CSA-2 for FDC-P1 colony-stimulating activity. Table 2 shows the effects of partially purified GM-CSA-2 from Con A spleen cm on FDC-P1 clonal growth in soft agar culture. GM-CSA-2 at a concentration of 80 U/mL stimulated FDC-P1 colony formation, but this did not approach the stimulation observed with IL 3. The blank containing McCoy's 5A media plus additives and agar

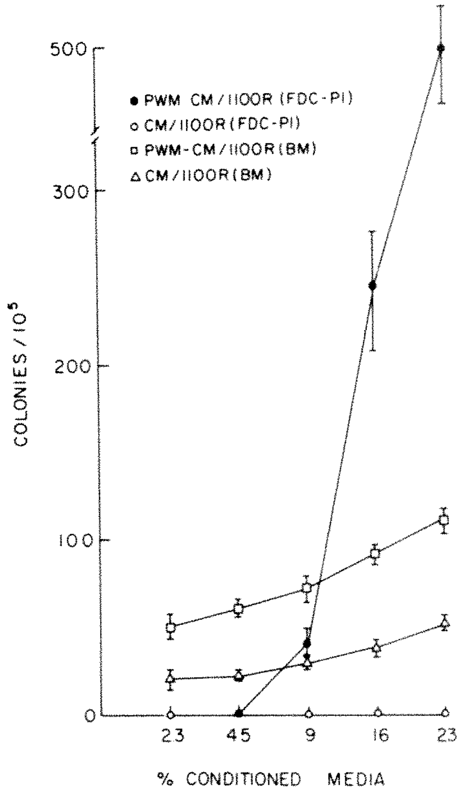

Fig 5. Assays of conditioned media from adherent cells of murine bone marrow cultures after exposure to irradiation and irradiation plus pokeweed mitogen. Concentration of pokeweed mitogen was 2.5 µg/mL. Media was collected after 48 hours of incubation and is a representative example of three separate experiments (see Materials and Methods). Colony-stimulating levels are expressed by mean numbers of both fresh murine marrow and FDC-P1 colony formation/10^5 target cells ±1 SEM. Three petri dishes were scored per group after seven days of incubation.

showed no colony formation. Recombinant GM-CSA also stimulated proliferation of FDC-P1 cells as assayed by ^{3}HtdR incorporation or clonal growth in agar (data not shown).

Effect of anti-GM-CSF antibodies on PWM/1,100 rad cm stimulation of FDC-P1 and murine marrow colony formation. Anti-GM-CSF antibody blocked the stimulation of both FDC-P1 and murine marrow colony growth by PWM/1,100 rad cm (Table 3). The inhibition was less for the marrow growth (53% ± 4.8%) but this is consistent with the presence of CSF-1, which is not inhibited by anti-GM-CSF (data not shown) and which does not stimulate FDC-P1 cells (see above). Thus the residual growth seen with murine marrow after GM-CSF blocking of PWM/1,100-rad cm is presumably due to CSF-1 in these preparations. The more complete inhibition of FDC-P1 proliferation by anti-GM-CSF suggests that GM-CSF is the primary stimulator of this cell type found in cm from PWM/1,100-rad stroma. In addition, an antibody to recombinant IL 3 was assessed for its ability to block FDC-P1 or murine marrow soft agar colony formation stimulated by PWM/1,100 rad cm in a fashion similar to that described for the anti-GM-CSF. No effect on marrow-(one experiment) or FDC-P1-(one experiment) stimulated growth was observed.

Table 2. Effect of GM-CSA-2 on FDC-P1 Clonal Growth in Soft-Agar Culture

Stimulus	FDC-P1 Colonies/10^5 Cells[*]
GM-CSA-2[†]	139 ± 16.7
IL 3[‡]	TNTC
Blank[§]	0

[*] In each group, three to four petri dishes were scored. These results are from three separate experiments.

[†] Preparations used in these studies were partially purified from supernatants of Con A-activated splenic lymphocytes (see "Methods"). One unit of activity was defined as amount of GM-CSA-2 in 1 mL, which was 50% of maximal stimulation of a GM-CSF-responsive cell population. GM-CSA-2 was plated at a concentration of 80 U/mL.

[‡] Interleukin 3 (IL 3) was used as a positive control in all experiments yielding colonies that were too numerous to count (TNTC). Preparations used in these studies had 0.2 ng of IL 3 per unit of activity. One unit of activity was defined as the amount of IL 3 that in 1 mL gives 50% of maximal tritiated thymidine incorporation into FDC-P1 cells in culture. IL 3 was plated at a concentration of 4 ng/mL.

[§] Blank media containing only McCoy's with additives (see "Methods") and 0.3% agar were used as negative controls and yielded no clonal growth.

Histochemical stains of stroma. Histochemical stains of irradiated stroma with and without exposure to PWM at 2.5 μg/mL showed no shift in cell types. We have previously reported on the staining characteristics of stroma exposed to 950 rad,[20] and the results with 1,100 rad alone were similar to our previously reported data except for a higher percentage of alkaline phosphatase positive cells in the present study.

DISCUSSION

Our present studies show that radioresistant adherent cells from murine Dexter cultures produce growth factors that stimulate FDC-P1 cells and murine marrow granulocyte-macrophage-megakaryocyte progenitors to proliferate.

The growth factor acting on FDC-P1 cells, which is increased by stromal irradiation and lectin exposure, appears to be GM-CSF. While CSF-1 is present in conditioned media from normal stroma, its levels are not increased by irradiation and/or lectin exposure, and, as noted above, pure CSF-1 does not stimulate FDC-P1 proliferation. The anti-GM-CSF antibody used in these studies blocks PWM/1,100-rad cm stimulation of FDC-P1 cells but does not block CSF-1 stimulation of marrow growth. Finally, we have confirmed the results of Hapel et al[27] showing that GM-CSF (recombinant or partially purified from Con A spleen cm) stimulates FDC-P1 proliferation as assessed by clonal agar culture or tritiated thymidine incorporation in liquid culture. The fail-

Table 3. Effect of Anti-GM-CSA on PWM/1,100 Rad Cm Stimulation of FDC-P1 and Bone Marrow Colony Formation

FDC-P1 cells‡

Stimulus	Antibody/Pre-immune Serum*	Colony (>10 cells)/ 2,000 cells
PWM/1,100 rad (31% final concentration)	Pre-immune serum	46.7 ± 5.4
	anti-GM-CSF	2.7 ± .7
GM-CSF (0.3 ng/mL)	Pre-immune serum	74.4 ± 4.7
	anti-GM-CSF	0.1 ± 0.1

ICR marrow cells§

Stimulus	Antibody/Pre-immune Serum†	Colony (>50 cells)/ 10,000 Cells
PWM/1,100 rad (33.3% final concentration)	Pre-immune serum	38.5 ± 3.5
	anti-GM-CSF	23 ± 5
GM-CSF (0.3 ng/mL)	Pre-immune serum	22 ± 1
	anti-GM-CSF	1.5 ± 1.5

*Final dilution of antibody/pre-immune serum was 1:6.

†Final dilution of antibody/pre-immune serum was 1:100. FDC-P1 10 cell colonies in Terasaki plates were counted at day 4 and BDF1 murine marrow colonies (>50 cells) at day 8 of culture.

‡The FDC-P1 data is from one experiment with nine replicate wells. This was confirmed in two separate experiments testing two different PWM/1,100-rad cm. The mean % inhibition (±1 SEM) of PWM/1,100-rad cm stimulated FDC-P1 colony formation caused by anti-GM-CSF was 87.3 ± 7. In the third experiment, growth was scored on a scale of 4+ (colonies so numerous that accurate counting was very difficult) to 0 (no growth). PWM/1,100-rad cm stimulated 4+ growth and exposure to anti-GM-CSF reduced this markedly to 0.5 to 1+ (few colonies).

§The data on ICR marrow is from one experiment utilizing 24-well Linbro plates and assessing replicate wells. This was confirmed in three other separate experiments using both BDF1 and ICR marrow cells and assessing two different lots of PWM/1,100-rad cm. The mean % inhibition (± are SEM) of PWM/1,100-rad cm stimulated colony formation caused by anti-GM-CSF for all experiments was 53 ± 4.8 (four experiments, six separate assessments).

ure of antibodies to IL 3 from two separate sources to block PWM/1,100-rad cm stimulation of FDC-P1 cells indicates that the FDC-P1 growth factor is not IL 3. Altogether these observations establish that GM-CSF is the FDC-P1 stromal-derived growth factor that increases after irradiation or lectin exposure.

These studies with FDC-P1 cells also indicate that the effects seen are probably direct and not mediated via accessory cells, since FDC-P1 cells do not proliferate in the absence of growth factors, and cm from FDC-P1 cells does not stimulate their own growth. In addition, we have shown here that PWM does not directly stimulate FDC-P1 growth (negative controls for Fig 2, data not presented).

The stromal growth factor for murine marrow, which is increased in the 1,100-rad and PWM/1,100-rad groups is probably also GM-CSF. CSF-1 is present in cm from Dexter culture but not increased by irradiation or lectin exposure. Anti-GM-CSF partially blocks PWM/1,100-rad cm marrow stimulation (53% ± 4.8% inhibition, Table 3), the residual marrow growth presumably being due to the presence of CSF-1. Consistent with this hypothesis are the preliminary observations that anti-CSF-1 antisera block PWM/1,100-rad cm stimulation of murine marrow colony formation by approximately 30%, while we have previously reported that marrow colony stimulation by cm from 950-rad stroma was inhibited from 46.6% to 92.4%[20] by exposure to anti-CSF-1 antisera. These data suggest that the primary CSA for murine marrow increased by lectin exposure is GM-CSF. In addition, colony formation stimulated by stromal-derived growth factors includes granulocyte, macrophage, megakaryocyte, and mixed lineage colonies, a spectrum of colony formation seen with either IL 3 or partially purified GM-CSF.[28] The anti-IL 3 studies cited above with FDC-P1 cells, a very sensitive IL 3 assay cell, plus the single experiment with marrow cells in which anti-IL 3 antisera did not block PWM/1,100-rad cm stimulation of marrow cell proliferation indicates that IL 3 is not the stromal-derived marrow stimulatory growth factor. Thus a radioresistant stromal cell appears to be stimulated by lectin exposure to release GM-CSF, which stimulates both FDC-P1 and a range of marrow progenitors. Finally, it should be noted that GM-CSF (with or without CSF-1) is capable of stimulating differentiation of all the differentiated hematopoietic lineages seen in Dexter marrow cultures: macrophages, granulocytes, and megakaryocytes.[28]

The identity of the radioresistant cell type generating these in vitro growth factors remains speculative. Two critical adherent cell types capable of supporting liquid culture hematopoiesis are seen after in vitro[20,29] or in vivo irradiation.[30] One cell type has the phenotype of a macrophage (phagocytic, acid phosphatase, and nonspecific esterase positive), while the other cell is a large alkaline phosphatase-positive epitheliod cell. Both cell types were Factor VIII negative and a small (<3%) fraction of cells did not fit either phenotype. In these studies we found no apparent shift in cell types with lectin exposure (Table 4). Thus the lectin responsive GM-CSF-producing cell types seem most likely to be either macrophages or the large alkaline phosphatase positive cells.

Previous studies from our laboratory have suggested that increases in myeloid stimulatory factors seen with irradiation of Dexter culture adherent cells may be due to removal of the negative feedback exerted by mature myeloid cells or removal of a population of cells that rapidly bind, utilize, or degrade these growth factors.[20] As with previous studies, our data on radiation dose response suggest an inverse correla-

Table 4. Results of Stromal Histochemical Stains Day 2 Post-XRT (% positive cells)†

Stain*	1,100 rad	1,100 rad + PWM (2.5 μg/mL)
Alpha naphthyl acetate (nonspecific esterase)	55	50
Acid phosphatase	95	97
Alkaline phosphatase	34	34

*Results were derived from one experiment, evaluating the stroma at day 2 post-XRT and PWM exposure. Eight hundred cells were scored for each stain.

†Cells stained at 2 to 4+ intensity on a scale of 0 to 4+ were scored as positive.

tion with FDC-P1 growth factor production and total amount of mature granulocytic elements present in the stromal layer.

The mechanism by which pokeweed mitogen stimulates stromal cells to produce increased levels of GM-CSF is not known. It seems probable that pokeweed mitogen selectively binds and stimulates a specific cell type remaining in the stromal layer after the exposure to irradiation, thereby increasing levels of GM-CSF. Alternatively, the pokeweed mitogen may act by eliminating an inhibitory phenomenon that may also increase colony formation. Studies by Gualtieri et al[20] demonstrated that conditioned medium from normal or irradiated stroma (without pokeweed mitogen) did not show differing levels of inhibitors. Also, in preliminary studies using conditioned media from irradiated cultures with and without pokeweed mitogen, we have found that when adding either of these conditioned media to purified CSF-1 there is no inhibition of growth. In fact, the conditioned medium from pokeweed mitogen-stimulated irradiated stroma, when added to pure CSF-1, actually increases both size and numbers of hematopoietic colonies, suggesting that a synergistic activity may be present in this conditioned medium. We have recently described an adherent cell line derived from murine Dexter cultures, termed TC-1,[31] which produces a CSF-1-dependent synergistic activity. At present it is uncertain whether this latter synergistic bioactivity may in part be responsible for the increased FDC-P1 and marrow colony formation seen with cm from irradiated lectin-exposed stroma.

In summary, we have shown that a radioresistant cell present in the adherent layers of long-term Dexter cultures responds to the lectin pokeweed mitogen by generating GM-CSF. CSF-1 is also produced by these adherent cells. These two regulators are sufficient to account for the differentiated hematopoietic progeny seen in this culture system: macrophages, granulocytes, and megakaryocytes.

Vitamin B12-Responsive Neonatal Megaloblastic Anemia and Homocystinuria With Associated Reduced Methionine Synthase Activity

By Lynnette J. Hallam, Margaret Sawyer, Arthur C.L. Clark, and Martin B. Van Der Weyden

We present findings on an infant with neonatal megaloblastic anemia, homocystinuria, and neurologic dysfunction that included developmental delay and tonic seizures. There was no methylmalonic aciduria. Cyanocobalamin therapy was accompanied by complete hematologic and neurologic recovery, diminished homocystine excretion, and subsequently normal neurologic development. Cultured fibroblasts and lymphoblasts showed a reduced methionine synthase activity and a growth requirement for methionine. Cobalamin incorporation by the patient's lymphoblasts was normal, but the proportion of cellular methylcobalamin in the patient's lymphoblasts and fibroblasts were markedly reduced and that of adenosylcobalamin normal. The reduced methionine synthase activity was independent of assay reducing (thiol) conditions, but normal levels of activity accompanied culture of the patient's lymphoblasts in medium with markedly increased cobalamin concentration. The characteristics of the reduced methionine synthase of our patient differ significantly from that of the previously described infant with cobalamin E disease and suggest that genetic heterogeneity may characterize this mutation.

© 1987 by Grune & Stratton, Inc.

IN HUMAN CELLS cobalamin (Cbl) occurs predominantly as either adenosylCbl or methylCbl. These cobalamins mediate reactions catalyzed by methylmalonylCoA mutase (adenosylCbl) in the generation of succinylCoA from methylmalonylCoA and that of methionine synthase (methylCbl) in the synthesis of methionine from homocysteine.[1]

Neonatal megaloblastic anemia consequent to inherited defects of cobalamin metabolism occurs either with a deficiency of the carrier protein transcobalamin II,[2] an obligatory mediator for cellular uptake of cobalamin, or with mutations leading to impaired intracellular synthesis of both adenosylCbl and methylCbl.[1] The latter states are accompanied by methylmalonic aciduria and homocystinuria as these two end products reflect intermediates normally metabolized by the cobalamin-dependent reactions in man. Recently Schuh and coworkers[3] described an infant with developmental delay, megaloblastic anemia, and homocystinuria but not methylmalonic aciduria who responded favorably to hydroxoCbl. The molecular basis for this syndrome was suggested to be failure of reduction of cobalamin bound to methionine synthase. In vitro findings included decreased fibroblast methylCbl but not adenosylCbl content and unique properties for methionine synthase, which exhibited normal activity at optimal but not at low assay reducing (thiol) conditions.[4] We describe here another infant with neonatal megaloblastic anemia and homocystinuria with reduced fibroblast and lymphoblast methionine synthase activities. This reduced activity, in contrast to that of the patient previously described, is independent of assay thiol concentration but dependent in part on the cobalamin levels of culture medium. These findings suggest that considerable genetic heterogeneity may characterize this newly described mutation of cobalamin metabolism.

CASE REPORT

The patient, a Caucasian male infant, was referred at the age of 10 weeks for investigation of anemia, hypotonia, and developmental regression. He was the first born of unrelated parents who had had no fetal losses. He was born at 38 weeks gestation, birth weight 3,180 g, and was in good condition at birth. His parents stated that he was never a very responsive baby but fed successfully from the breast and smiled and responded to his parents at about six weeks. At that time he had a febrile illness with diarrhea and vomiting lasting about one week, after which he became unresponsive and unsmiling. On admission to the hospital at 10 weeks he was a pale, floppy, unresponsive infant, height 59 cm, weight 4,730 g, and head circumference 39.3 cm. The liver was palpable 3 cm below the costal margin, the spleen not palpable, and lymph nodes not enlarged. Despite his generalized hypotonia, deep tendon reflexes were present and symmetrical, and no other neurologic abnormalities were noted. However, during the subsequent three weeks he developed truncal spasticity with head retraction and spine extension when disturbed, and on the fifth hospital day he had a generalized seizure. Three further seizures followed until he was given phenobarbitone, after which these ceased. Investigations on admission revealed anemia with hemoglobin 7.7 g/dL, hematocrit 21%, MCV 101 fl, MCH 35.5 pg, MCHC 53.2 g/dL, reticulocytes 3.5%, obvious anisocytosis, macrocytosis and poikilocytosis. The WBC was $8.6 \times 10^9/L$, neutrophils 27% with hypersegmentation, lymphocytes 71%, eosinophils 2%. Platelets were $719 \times 10^9/L$. Bone marrow was markedly cellular and megaloblastic. High voltage electrophoresis of the urine showed greatly increased homocystine and increased serine, alanine, leucine, and ethanolamine. Methylmalonic acid was not detected, and gas liquid chromatography showed a normal organic acid pattern. Plasma amino acid analysis was not performed before treatment. Two weeks after the first dose of vitamin B12, no homocysteine was detected in the plasma while methionine was 4 µmol/L (n, 5 to 34). Red cell folate was 1,280 nmol/L of packed cells (n, 230 to 2,200), serum folate 41 nmol/L, and B12 117 pmol/L (n, 160 to 500). Liver and renal function tests were normal. Cerebral ultrasound examination showed no abnormality, and an EEG showed medium voltage

with no consistent asymmetry, focal, or epileptiform features. His mother's serum folate and B12 were normal, and she had no antibodies to intrinsic factor. Transcobalamin II deficiency was excluded by normal findings for patient's serum mediated 57Co-cyanocobalamin uptake by normal lymphoblasts and serum 57Co-cyanocobalamin elution pattern with gel chromatography. One week after admission treatment was begun with both folate and B12, the latter as 1,000 μg of cyanocobalamin intramuscularly (IM) daily. Reticulocytes peaked at 23% on the fifth day, and there was progressive rise in hemoglobin and return toward normal of red cell changes. On treatment his general health improved, his muscle tone returned to normal, and there were no further seizures. Homocystine was no longer detected in his urine. Anticonvulsants were discontinued at six months, and B12 was reduced to 1,000 μg twice a week at 12 months. At 2 years folic acid was discontinued. Developmental assessment at 3 years is within normal limits in all modalities. A female sibling was born 2 years later. She was physically and hematologically normal at birth. At 6 weeks she had a Hb 12.7 g/dL, MCV 100 fl, with normal red cell morphology. She made good progress until her sudden cot death at 9 weeks. Post mortem examination failed to reveal the cause of death. Attempts to establish Epstein-Barr virus (EBV)-transformed lymphoblasts from this individual were not successful.

MATERIALS AND METHODS

Cell lines. Human skin fibroblasts from the patient and normal individuals were routinely grown in Eagle's minimum essential medium (CS Laboratories, Parkville, Australia) with 10% fetal bovine serum (FBS Flow Laboratories, Australia). EBV-transformed lymphoblast cell lines were established from the patient, mother, father, and normal individuals as described previously.[5] All lymphoblast cell lines were maintained in exponential growth in RPMI 1640 medium (Flow Laboratories) supplemented with 10% FBS. The concentration of methionine under normal culture conditions is 0.1 mmol/L (15 mg/L) and vitamin B12 3.7 nmol/L (5 μg/L). In experiments with modifications of concentration of vitamin B12, folate, or methionine in the culture medium, cells were grown in a modified RPMI 1640 medium (K-C Laboratories, Kansas City) with the appropriate vitamin or amino acid added at the indicated concentration. Fibroblast and lymphoblast growth studies were initiated at a cell density of 2×10^5/mL and 5×10^5/mL respectively with the indicated culture medium conditions, and cell counts were performed as previously described at 96 hours using trypan blue exclusion as the index of viability.[6]

Fibroblasts were harvested by treatment with 0.25% trypsin (Flow Laboratories) for one minute at 37°C and subsequent inactivation with FBS.

Enzyme assays. Lymphoblasts or confluent fibroblasts were harvested as described, centrifuged at 1,000 g for 10 minutes at 4°C, and washed thrice with phosphate-buffered saline (PBS). Extracts of cells in appropriate buffers, usually 10 mmol/L Tris HCL pH 7.4 were performed by either freeze thawing in liquid nitrogen or by sonication. Cell extracts were centrifuged at 1,500 g for 10 minutes at 4°C and supernatant used for assay. Protein was determined using bovine serum albumin as standard by the method of Lowry et al.[7]

Thymidylate synthase,[8] serine hydroxymethyltransferase[9] and 5,10-methylene tetrahydrofolate (THF) reductase[10] were measured as previously described. Methionine synthase was measured by the method of Kamely et al with minor modifications.[11] Activity was determined by the formation of 14C-methionine from 14C-5 methyl THF (5-MTHF) in the dark. The standard reaction mixture contained in a total volume of 0.2 mL: 130 mmol/L sodium phosphate buffer pH 7.4 (Ajax Chemicals, Australia), 200 mmol/L B-mercaptoethanol (BDH Chemicals, Australia), 275 μmol/L S-adenosyl methionine (SAM) (Boehringer Mannheim, Germany), 50 μmol/L methylcobalamin (MeCbl) (Sigma Chemicals, St Louis), 500 μmol/L DL-homocysteine (Sigma Chemicals, St Louis), prepared just before use from the thiolactone derivative, 600 μmol/L (14C) 5-MTHF 2 μCi/μmol (Amersham, England) and 150 to 160 μg of cell extract. The assay control was minus the addition of MeCbl and SAM, and activity obtained with the omission of MeCbl was that of the holoenzyme. Incubation was in the dark at 37°C for 60 minutes. The reaction was terminated by adding 0.8 mL of ice-cold water. The mixture was passed through Bio-Rad AG-1X8 columns (Bio-Rad Laboratories, Richmond, CA), and the columns were washed with an additional 1.0 mL of water. The radioactivity in the pooled effluent was determined in a liquid scintillation counter. Enzyme-specific activities are expressed as nmol of product formed/hour/mg protein. Methionine synthase was assayed routinely under aerobic conditions as described above but was also determined anaerobically by flushing the reaction mixtures with nitrogen, which were then sealed during the incubation.

Intact cell assays. Incorporation of 14C-5MTHF into acid precipitable material was performed according to the method of Mellman et al,[12] and incorporation of 14C-propionate (Amersham, England) into acid precipitable material was as described by Willard et al.[13] Incorporation of 57CO-cyanocobalamin (Amersham) 0.1 ng/mL was performed at two hours and 72 hours as described by Mellman et al[14] and for fractionation of intracellular cobalamin cells were extracted according to the method of Linnell et al[15] and cobalamins separated on a SP Sephadex C-25 column (Pharmacia, Sweden) in the dark, as previously described.[4]

RESULTS

Methionine synthase activity in patient's cells. Altered cellular cobalamin metabolism in the patient's cells was explored by determining the incorporation of radioactivity from 14C-labeled propionate and methyl THF into protein of patient and control lymphoblasts precipitated by trichloroacetic acid. Incorporation by patient's cells of radioactivity from 14C-propionate was normal, but that from 14C methylTHF was significantly reduced (Table 1), suggesting a defect of methionine synthesis without an abnormality in the function of methylmalonylCoA mutase. The level of activities of enzymes of patient's lymphoblasts that are involved in thymidylate synthesis, namely thymidylate synthase, 6.5 ± 1.4 nmol/hour/mg protein (mean, SE) serine hydroxymethyltransferase 257 ± 61 nmol/hour/mg protein, or that of 5,10 methylene THF reductase 2.3 ± 0.3 nmol/hour/mg protein were comparable to the corresponding values of those activities in control lymphoblasts: 6.7 ± 0.6, 386 ± 36, and 1.8 ± 0.2 nmol/hour/mg protein. Methionine synthase was measured in patient and control cell extracts with and

*Values given are the mean ± SE, in excess of six separate determinations.

†Fibroblasts were cultured in Eagle's minimum essential medium supplemented with 10% FBS. Cells were harvested upon confluency and assayed for methionine synthase activity as described in the text. Lymphoblasts were cultured in RPMI 1640 medium supplemented with 10% FBS and cells harvested 48 hours after initiation of culture and assayed for methionine synthase activity.

‡Values significantly different from control levels at $P < 0.01$, Student's *t* test.

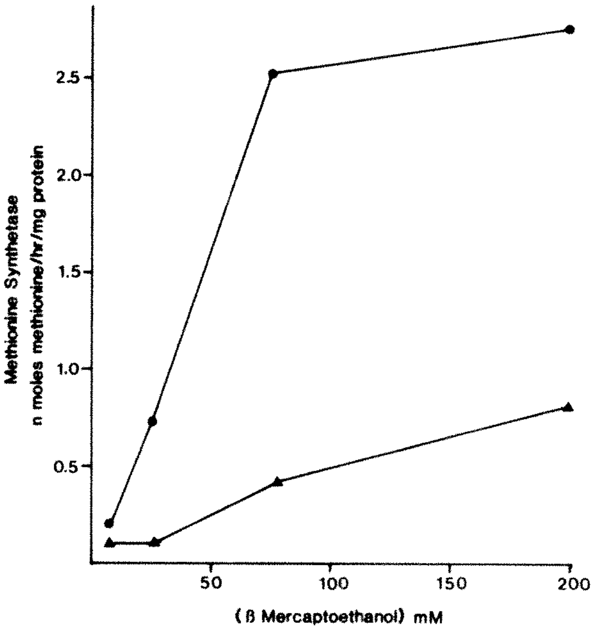

Fig 1. Levels of methionine synthase of patient and control lymphoblasts assayed with varying B mercaptoethanol concentrations. Lymphoblasts were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum, cells were harvested and assayed for methionine synthase as described in Materials and Methods, with B mercaptoethanol concentration ranging from 7.5 to 200 mmol/L. The values given are the mean of duplicate determinations. ●, Control; ▲, patient.

without added cobalamin (Table 2). Both holoenzyme and total enzyme activities were reduced in patient's fibroblasts and lymphoblasts. This reduced methionine synthase activity was evident in patient's lymphoblasts in culture at all intervals up to 96 hours. Assay of methionine synthase of patient and control lymphoblasts under anaerobic conditions showed no significant difference to that under aerobic conditions. Methionine synthase of control lymphoblasts were 2.2 and 0.9 (holoenzyme) nmol/hour/mg protein (aerobic) and 2.3 and 0.6 (anaerobic). Corresponding values for patient lymphoblasts were 0.36 and 0.21 (holoenzyme) nmol/hour/mg protein (aerobic) and 0.40 and 0.30 nmol/hour/mg protein (anaerobic). In data not shown, mixing control and patient lymphoblast extracts yielded the expected levels of methionine synthase activity, excluding the possibility of inhibition or, alternatively, activation of patient's reduced methionine synthase activity by constituents of control extracts.

Effect of alteration of assay conditions on methionine synthase of patient's cells. Rosenblatt et al[4] have demonstrated that methionine synthase in the previously described patient with megaloblastic anemia and homocystinuria was normal at conventional thiol concentrations. The effect of varying assay concentrations of dithiothreitol (DTT 0.2 to 25 mmol/L) and B mercaptoethanol, (7.5 to 200 mmol/L) were determined with lymphoblast extracts of the current patient. In both instances at all concentrations of thiol assayed the patient's methionine synthase activities (Figs 1 and 2) were significantly lower than those of control lymphoblasts. For both patient and control lymphoblast extracts, methionine synthase activity at the maximal concentration of DTT (25 mmol/L) was approximately four times that observed with B mercaptoethanol (200 mmol/L), suggesting that the reducing conditions produced by these thiol reagents are neither equivalent nor a unique interaction of DTT with methionine synthase. Methionine synthase of patient and control fibroblasts were also assayed with varying concentrations of B mercaptoethanol: 5, 75 and 200 mmol/L. With these thiol concentrations, control fibroblast methionine synthase activities were 0.17, 1.45, and 2.5 nmol/hour/mg protein. Corresponding values for patient fibroblast methionine synthase were 0.04, 0.39, and 0.8 nmol/hour/mg protein. In data not shown, increasing the assay concentration of methylcobalamin (up to 50-fold), S-adenosyl methionine (up to fivefold), and 5 methylTHF (up to fivefold) did not significantly alter the reduced methionine synthase activity exhibited by patient cell extracts. In addition, substitution of methyl cobalamin by hydroxocobalamin or cyanocobalamin in the assay system produced no significant differences.

Effect of varying culture concentration of cobalamin on methionine synthase activity. The methionine synthase activities for control and patient lymphoblasts cultured with either varying cobalamin compounds or concentration are shown in Table 3. Control lymphoblasts cultured with increasing concentration of cyanocobalamin (0.5 μg/L, 0.375 nmol/L to 500 μg/L, 375 nmol/L) exhibited a fivefold increase in methionine synthase, and the enzyme levels with hydroxoCbl or cyanoCbl at the higher cobalamin culture concentration used were comparable (Table 3). Patient's lymphoblasts cultured under identical conditions showed a twofold increase in methionine synthase activity, and this activity level was now in the normal range.

Accumulation and distribution of labeled cobalamin and effect of methionine culture deprivation on cell growth. The accumulation of label from 57Co-cyanocobalamin in patient and control lymphoblasts after two hours or 24 hours

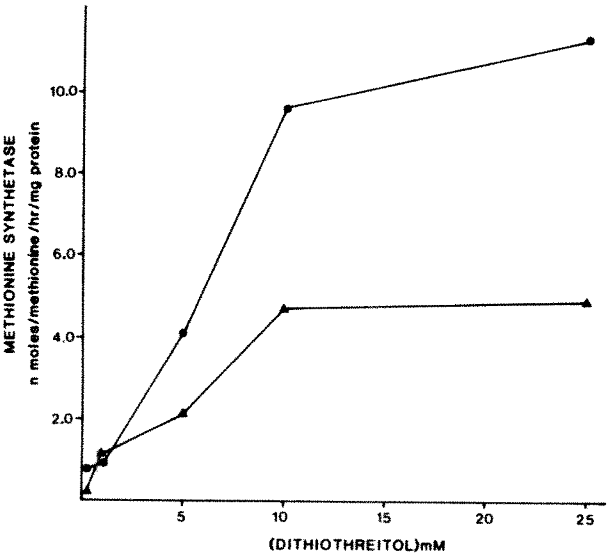

Fig 2. Levels of methionine synthase of patient and control lymphoblasts assayed with varying dithiotreitol concentrations. Lymphoblasts were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum, and cells were harvested and assayed for methionine synthase as described in Materials and Methods, with dithiothreitol ranging from 0.2 to 25 mmol/L. The values given are the mean of duplicate determinations. ●, Control; ▲, patient.

in culture was comparable: at two hours patient 3.2×10^3 cpm, control 2.4×10^3 cpm/10^6 cells; at 24 hours patient 19×10^3 cpm, control 17×10^3 cpm/10^6 cells. The distribution of methylCbl and adenosylCbl in human lymphoblasts showed that in contrast for fibroblasts the major cellular cobalamin is adenosylCbl, but the concentration of methylCbl in patient's lymphoblasts and fibroblasts was markedly reduced (Table 4). The patient's cells exhibited reduced growth rates when cultured in methionine-replete medium or when methionine was replaced by homocysteine. When 2×10^5/mL control and patient fibroblasts were plated in complete medium, growth at 96 hours for control cells was $9 \pm 0.3 \times 10^5$ (SEM)/mL and for the patient's cells $5 \pm 0.2 \times 10^5$/mL. When homocysteine (0.2 mmol/L) was substituted for methionine in the media, growth at 96 hours was $8 \pm 0.5 \times 10^5$/mL for control fibroblasts and $3 \pm 0.2 \times 10^5$/mL for the patient fibroblasts. Lymphoblasts were also studied. Both control and patient lymphoblasts cultures were initiated at a cell density of 0.5×10^6 cells/mL. Growth at 96 hours in methionine replete medium was $3.2 \pm 0.3 \times 10^6$ (SEM)/mL for the control lymphoblasts and $2.4 \pm 0.1 \times 10^6$/mL for patient's lymphoblasts. Both the control and patient lymphoblasts showed a preferential growth requirement for methionine with the patient's lymphoblasts exhibiting no increase in cell numbers in the absence of methionine. When homocysteine was substituted for methionine, control lymphoblasts' density at 96 hours had increased to $0.9 \pm 0.1 \times 10^6$ (SEM)/mL, whereas the patient's lymphoblast density at 96 hours was $0.4 \pm 0.1 \times 10^6$/mL.

*Lymphoblasts were cultured in standard RPMI 1640 supplemented with 10% fetal calf serum with varying concentrations of cyanocobalamin or hydroxocobalamin as indicated. Cells were harvested at 48 hours and assayed for methionine synthase activity as described in the text.

†Lymphoblasts were cultured in RPMI 1640 medium without or with hydroxocobalamin at concentration of 3.75 nmol/L and methylTHF 2μmol/L, harvested at 48 hours, and assayed for methionine synthase as described in the text.

‡Figures in parenthesis are holoenzyme values.

DISCUSSION

Inherited defects of cobalamin metabolism resulting in megaloblastic anemia and homocystinuria include the mutations of congenital methylmalonic aciduria-homocystinuria. On the basis of biochemical and genetic complementation studies, these disease states represent at least two different genetic entities termed CblC and CblD mutations, which both involve an assumed defect in Cob(III)alamin reductase.[14-17] This activity reduces the charge of the cobalt of cobalamin from +3 to +2, an event that normally occurs after cobalamin enters into the cell and precedes the formation of both adenosylCbl and methylCbl. Thus common to these mutations is the inability of affected cells to accumulate cobalamin as adenosylCbl and methylCbl and reduced holoenzyme activities of methylmalonylCoA mutase and methionine synthase.[1] Clinical findings include methylmalonic aciduria, homocystinuria, neurologic disorders, and a variable incidence of megaloblastic anemia confined to individuals with CblC mutation.[1] Cells of our patient (1) were not defective in accumulating cobalamin but exhibited decreased methyl Cbl but not adenosylCbl content, (2)

*Results expressed as % of total cobalamin in cell extracts following growth for 72 hours in RPMI 1640 medium containing 57Co-cyanocobalamin (0.1 ng/mL). Values given are means of two separate determinations in duplicate.

utilized the methyl group of methylTHF less effectively than normal cells, and (3) incorporated the radio label from 14C propionate into protein at normal rates. In addition, our patient exhibited megaloblastic anemia with homocystinuria but not methylmalonic aciduria. These findings exclude CblC or CblD mutations and are identical with those reported for the patient with CblE disease. At variance are the differing characteristics of methionine synthase. Specifically, the reduced methionine synthase activities of our patient's lymphoblasts and fibroblasts were not normalized with optimal assay reducing conditions, either with DTT or B-mercaptoethanol. In addition, increasing substrate concentrations of methylTHF, methylCbl, or S-adenosylmethionine had no effect on the reduced activity. Although these findings suggest that our patient with altered methionine synthase activity may have a defect at the same locus as that of the previously described patient with congenital homocystinuria and abnormal methionine synthase activity,[3] only genetic complementation studies will resolve this question. That this altered methionine synthase is of significance for intact cells is suggested by the reduced methylCbl content of the patient's lymphoblasts and fibroblasts and an impaired growth rate of patient fibroblasts and lymphoblasts when methionine was substituted in culture medium by homocysteine. The mechanisms involved in methionine-dependent cell growth are controversial and evolving.[18,19] In the absence of extracellular methionine, this amino acid in cells is generated in human cells from either homocysteine by methionine synthase or by a series of reactions from the methylthio-containing portion of methylthioadenosine, a byproduct of polyamine metabolism.[20,21] Methionine for cell growth is potentially a summation of the contributions of these two pathways. The differing growth capacity of our patient's cells in culture when methionine has been replaced by homocysteine reflects in part the reduced methionine synthase activity of these cells and the relative contribution of this activity to the cellular methionine pool. Changing culture cobalamin conditions produced differing effects for the patient's and control lymphoblasts' methionine synthase activity. An increase in the concentration of cobalamin added to the culture medium was accompanied by a fivefold increase in this activity of control lymphoblasts compared with a twofold change for patient's cells cultured under identical conditions. Limiting cobalamin in the culture medium was accompanied by greater degrees of reduction of patient's activity, and it is of some interest that our patient's serum B12 on presentation was suboptimal. Although the magnitude of increase of patient's methionine synthase with increased cobalamin in the culture medium was less than that exhibited by control lymphoblasts, the absolute level of activity achieved by the patient was of the same order as in normal cells grown under standard conditions for cobalamin. This finding may have in vivo significance since both the homocystinuria and megaloblastic anemia responded completely to large doses of cyanoCbl, and it is feasible that this is mediated by augmentation of the reduced activity in vivo. The molecular basis for cobalamin-related changes in methionine synthase of culture cells is not entirely clear. It is independent of protein synthesis and probably reflects stabilization of enzyme by cobalamin with decreased enzyme turnover.[11] If this is so, the differing pattern of response of the patient's methionine synthase to cobalamin concentration in culture suggests a fundamental difference for mutant activity. Only purification and characterization of the enzyme will satisfy this hypothesis. As the two described patients with neonatal megaloblastic anemia, homocystinuria, and altered methionine synthase activity exhibited neurologic features, including seizures and developmental delay, the impact of altered cobalamin metabolism on the developing neurologic system deserves some comment. Whether in hereditary disorders such as transcobalamin II deficiency, CblC, and now CblE mutation or the acquired defects of vitamin B12 in breast-fed infants of vegan or pernicious anemia mothers,[5,22] the accompanying neurologic syndromes are characterized by their diversity if one sets aside the background of failure to thrive, listlessness, and irritability. Possibly the specific neurologic syndromes depend primarily on the developmental stage of the infant at the onset of vitamin deficiency. Whatever the manifestations, failure to diagnose the specific defect and to institute appropriate therapy can have dire consequences for the infant's ultimate neurologic status,[22-24] whereas early recognition is associated with a favorable outcome as illustrated in our patient.

ACKNOWLEDGMENT

We would like to thank I. Jack and Dr G. Young for establishing the fibroblast and lymphoblast cell lines of the patient and for their continuing help and advice and Maureen Cross for excellent preparation of the manuscript.

Correlation of Drug-Perturbed Marrow Cell Growth Kinetics and Intracellular 1-B-D-Arabinofuranosylcytosine Metabolism With Clinical Response in Adult Acute Myelogenous Leukemia

By Judith E. Karp, Ross C. Donehower, Gregory B. Dole, and Philip J. Burke

To define the relationship between leukemic cell growth, intracellular metabolism of 1-B-D-arabinofuranosylcytosine (ara-C), and the clinical response to timed sequential induction therapy with ara-C in adult acute myelogenous leukemia (AML), growth kinetic and biochemical pharmacologic determinants were examined in AML bone marrow populations. Leukemic blasts from 45 previously untreated patients obtained prior to therapy were cultured in vitro in autologous pretreatment serum (APS) and in serum containing drug-induced humoral stimulatory activity (HSA). Cell populations cultured in HSA demonstrated both increased proliferation, as measured by both [^{3}H]dThd incorporation into DNA and [^{3}H]dThd leukemic blast labeling index, and greater [^{3}H] ara-C leukemic blast labeling index relative to cells maintained in APS. HSA-cultured marrow cells from the 31 patients who achieved complete remission with ara-C-containing therapy demonstrated enhanced intracellular formation of ara-C 5′-triphosphate over three hours and retention of this active form during one subsequent hour in drug-free medium relative to cells maintained in APS. In contrast, cells from the 14 nonresponsive patients demonstrated no such HSA-induced increases in intracellular ara-C metabolism. These studies of human AML marrow cells identify behavior patterns of ara-C activation and net metabolism in the kinetically perturbed, proliferative state that may discriminate clinical sensitivity from clinical resistance to ara-C-based timed sequential therapy. Sensitive AML populations behave similarly to normal hematopoietic cohorts, with direct linkage of HSA-perturbed growth and pharmacologic parameters, while refractory cells demonstrate uncoupling of these determinants in the growth-stimulated state. These in vitro measurements may further serve as a template for prediction of clinical outcome to timed sequential therapy with ara-C, where both pharmacologic and cytokinetic determinants of response are intrinsic to the success of the designed drug scheduling.

© 1987 by Grune & Stratton, Inc.

THE PHARMACOLOGIC basis for 1-B-D arabinofuranosylcytosine (ara-C) cytotoxicity rests on its intracellular conversion to the active metabolite, ara-C 5′-triphosphate (ara-CTP), which acts as a competitive inhibitor of DNA polymerase[1-3] and is directly incorporated into DNA, with further deleterious effects on DNA structure and function.[4-6] Therefore the extent to which ara-C is metabolized to ara-C 5′-triphosphate (ara-CTP) and the intracellular distribution of this active metabolite in blast cells prior to treatment have been examined in vitro as possible predictors of clinical drug sensitivity for acute myelogenous leukemia (AML) cell populations.[7-14] Such studies have not consistently correlated closely with clinical outcome, suggesting that measurement of an isolated determinant of ara-C activity is not sufficient to discriminate responders from nonresponders. The inability of these single-parameter studies to predict response may relate not only to biological patient-to-patient heterogeneity, which limits the applicability of specific assay systems,[15-18] but perhaps also to cellular heterogeneity within an individual tumor population that may obscure detection of drug-resistant cell subpopulations.[19-22]

One factor that may have major impact on overall ara-C cytotoxicity is the growth characteristics of the target cell population. ara-C is a cell cycle-dependent antimetabolite with its greatest toxicity directed against cells in S phase.[23] As such, the overall mechanism of action and net toxic effects should depend on the fraction of proliferating cells in the treated population at the time of drug exposure. In this light, growth kinetic heterogeneity, a characteristic of pretreatment leukemic cell populations,[21,24-30] may in part account for the apparent failure of measurements of intracellular ara-C biochemical pharmacology alone to accurately predict net drug effect and clinical response.

The development of timed sequential therapy for adult AML at the Johns Hopkins Oncology Center is based on the study of drug-primed cell growth kinetics in several systems[25,26,29,31-37] and is designed to overcome pretreatment growth heterogeneity by recruitment of residual leukemic cells into DNA synthesis following initial cytoreduction. Our studies have shown that after an initial dose of cytotoxic therapy, various measures of cell proliferation reach a maximum at a predictable time following the initial drug(s).[26,29,32,33,35,37] This growth perturbation in both man and rodent is associated with induction of serum activities that promote bone marrow cell DNA synthesis in vitro.[26,31,38-41] This maximally detected humoral stimulatory activity (HSA) also occurs at a predictable time following initial aplasia-producing drug administration and coincides with the increased [^{3}H]dThd labeling index (LI) and clonogenicity of recovering normal granulocytic and malignant hematopoietic precursors in vivo.[24,26,29,32,33,35,38,41] The drug-induced kinetic homogeneity and its relation to improved antitumor effects of ara-C have been demonstrated in vivo in leukemia-bearing rodents, where the detection of HSA and peak drug-induced tumor LI have been correlated with enhanced therapeutic effects of ara-C given in a sequence based on this predictable increase in residual tumor proliferation.[24,26,34,39]

To define the relationship between perturbed cell growth and intracellular ara-C metabolism in human cells, we examined growth kinetic and ara-C biochemical pharmacologic determinants in HSA-perturbed normal human bone marrow populations.[42] Those studies demonstrated the coupling of induced cell growth with enhanced ara-C activation and metabolism in the kinetically perturbed, proliferative state. In our present studies we have now examined growth kinetic and biochemical pharmacologic determinants in pretreatment human AML bone marrow cell populations in vitro, both in the baseline milieu of autologous pretreatment serum (APS) and in the kinetically perturbed state in the presence of drug-induced HSA, and have been able to identify patterns in these in vitro studies that appear to correlate with clinical sensitivity and clinical resistance to ara-C-based timed sequential therapy.

MATERIALS AND METHODS

Patients and therapy. From April 1984 through January 1986, a total of 59 newly diagnosed, nonpreviously treated (NPT) adults (median age 54 years, range 19 to 76) with the diagnosis of AML (myeloid, myelomonocytic, monocytic, megakaryocytic) were consecutively admitted to the Adult Leukemia Service of the Johns Hopkins Oncology Center for intensive timed sequential induction chemotherapy with ara-C and daunorubicin[35,36] and were evaluated with respect to clinical outcome following treatment. All patients received antileukemic therapy as part of clinical investigation approved by the Joint Committee on Clinical Investigation of the Johns Hopkins University School of Medicine in accord with assurance approved by the US Department of Health and Human Services, and following full informed consent to participate in active investigative therapy. Of these 59 NPT patients, a total of 45 (76.3%) were studied and were considered able to be evaluated with respect to the interrelationship of growth, pharmacologic parameters, and clinical response. Five (8.5%) of the 59 patients did not survive induction chemotherapy and were therefore not considered able to be evaluated for response.[35,36] An additional nine (15.3%) patients did not have pretreatment studies performed; three of these patients had severe myelofibrosis and the remaining six required emergency institution of cytoreductive therapy for leukostasis. Of the 59 consecutively admitted patients, 38 (64.4%) achieved complete remission (CR) while 16 (27.1%) had no response (NR) to induction therapy. Of the 45 patients studied and evaluated for in vitro growth and ara-C pharmacology plus clinical outcome, all had at least 80% malignant marrow blasts prior to treatment. CR of at least 3-months duration, defined by Acute Leukemia Group B criteria, was achieved following induction therapy in 31 (69%) of these NPT adults; the remaining 14 patients had NR to timed sequential therapy (or CR less than 3 months).

Bone marrow cell cultures. Marrow cells were obtained from all 45 patients prior to therapy by routine needle aspiration, collected in RPMI 1640. To ensure that marrow cells were free from contamination by peripheral blood blasts, marrow spicules were isolated, and cells isolated from the spicules were dispersed as single cells by drawing through a 25-gauge needle. Each cell suspension was prepared and studied individually. Whole marrow cell suspensions (1×10^6 cells/mL for incorporation and labeling index studies; 2.5×10^6 cells/mL for ara-CTP formation and retention studies) were cultured in replicate in sterile plastic Falcon 2063 and 2057 tubes with specific sera at 15% concentration. Cultures were maintained in a humidified atmosphere containing 5% CO_2 at 37°C.

Specific sera collection. Sera were obtained from all newly diagnosed AML patients. Prior to treatment, 100 mL of whole blood were collected from each patient and allowed to clot and the serum was separated under sterile conditions and stored immediately at −70°C. These sera were studied in culture with bone marrow cells from the same patient (autologous pretreatment sera, APS).

Drug-induced HSA-containing sera were obtained from patients with AML undergoing aplasia-inducing chemotherapy at the predicted peak of maximal detection.[31-33,35,38,40,43] To obtain adequate amounts of HSA for these in vitro studies, post-treatment sera from ten leukemia patients achieving CR, which maximally stimulated in vitro marrow cell [^{3}H]dThd incorporation relative to the effects of normal serum, were pooled.[32,33,42,43] All sera were stored at −70°C until use.

[^{3}H]dThd incorporation assay. The method for assaying [^{3}H]dThd incorporation into marrow cell DNA has been described previously[31,38,40-43] and determines both the proliferative status of those marrow cells and the relative growth kinetic changes induced by perturbing the initial pretreatment cell population with HSA during 18 hours culture. In brief, marrow cell suspensions (1×10^6 cells/mL) were incubated with 15% specific serum plus [^{3}H]dThd 1 μC/mL (methyl-^{3}H, New England Nuclear, Boston; specific activity 2 Ci/mmol) at culture initiation. Following 18 hours incubation, triplicate cultures were terminated by immersion in ice, and the contents of each tube was collected under vacuum on glass fiber filter. Each tube was washed with 0.9% NaCl solution, the acid-insoluble materials on the filter were precipitated with cold 5% trichloracetic acid, and the precipitate was washed three times with absolute ethanol. The dry filter was transferred to a screw-top vial to which 6 ml of scintillation fluid (Instagel) were added, and the amount of incorporated isotope was counted in a liquid scintillation spectrometer. Results are expressed as pmol dThd incorporated/10^6 cells in specific sera.

Labeling index (LI) determinations. [^{3}H] ara-C and [^{3}H]dThd leukemic blast LI were determined following 18 hours of culture in APS and HSA, as described previously.[25,26,29,33,37,38,42] In brief, aliquots of monodispersed AML marrow were incubated with 15% specific serum and either [^{3}H] ara-C 1 μCi/mL (specific activity 11.2 Ci/mmol) or [^{3}H]dThd 0.1 μCi/mL (specific activity 2 Ci/mmol) for 75 minutes at 37°C in a humidified atmosphere containing 5% CO_2. Following incubation cells were washed carefully in phosphate-buffered saline (PBS) three times and lightly cytocentrifuged (1,000 × g, five minutes) onto slides coated with gelatin. Autographs were prepared with Kodak NTB-2 photographic emulsion, exposed for 21 days, developed, and stained with Giemsa. The [^{3}H] ara-C and [^{3}H]dThd LI of leukemic marrow cells were determined by counting the number of cells per 1,000 that contain >5 grains overlying the nucleus. Background labeling is estimated by the number of grains present in a cell-free area equivalent to the area of the leukemic blast nucleus. Background labeling is negligible for [^{3}H]dThd (≤ 1 grain) and is ≤ 2 to 3 grains for [^{3}H] ara-C. Cells labeled with [^{3}H] ara-C generally contain ≥ 10 grains overlying the nucleus, and cells labeled with [^{3}H]dThd generally contain ≥ 25 grains. Results are expressed as percentage of labeled blasts. The standard error for this method is ±1% in our laboratory.

Intracellular ara-CTP levels. [^{3}H] ara-C (5,6-^{3}H cytosine; Moravec Biochemicals, City of Industry, CA; specific activity 18 Ci/mmol) was added to duplicate cultures at time 0 and to cells in APS and HSA following 18 hours incubation (Time 18) to yield a final ara-C concentration of 1 μmol/L. Because ara-C uptake is linear over one hour and intracellular ara-CTP formation with subsequent retention continues with a plateau over the following one to two hours,[8-10] cultures were incubated at 37°C in humidified 5% CO_2 for three hours, then centrifuged at 5,000 × g for five minutes, and the ara-C-containing medium was decanted. Half of the cultures were resuspended in fresh medium without drug and were returned to the incubator to be analyzed one hour later for ara-CTP retained

following the end of drug exposure in the manner described below. The other half of the cultures were subjected to a 0.8 mol/L perchloric acid precipitation. Following centrifugation the supernatant liquid containing the acid-soluble cell constituents was transferred to another tube where it was neutralized with KOH to a pH of approximately 7. The insoluble salt was removed by centrifugation, and the second supernate was immediately ready for high performance liquid chromatographic (HPLC) analysis of ara-C nucleotide levels. ara-CTP levels were measured on a Waters HPLC system with an M-45 pump, U6K injector, and model-440 variable wavelength absorbance detector set at 254 nm to monitor the separation (Waters Association, Milford, MA). The isocratic separation used 0.4 mol/L KH_2 PO_4, pH 3.1, over a Whatman Partisil 10-SAX anion exchange column (Whatman, Clifton, NJ) with an elution time of six minutes and a flow rate of 3 mL/min. ara-CTP levels were quantitated by the recovery of ara-C-associated counts at the established retention time for ara-CTP and were expressed as pmol nucleotide/10^6 cells. Coefficient of variation for replicate samples is $\leq 10\%$ in our laboratory. This method is similar to those widely used for chromatographic separation of nucleotides.[10-12,44] The efficiency of the extraction of nucleotide triphosphates using this method was examined by adding a known quantity of radiolabeled triphosphate (deoxycytidine 5′-triphosphate [5-^{3}H], 15 Ci/mmol; New England Nuclear, Boston) to an untreated cell preparation. The extract was then analyzed by HPLC as described. Using this method 87.0% ± 6.0% of the standard remained in triphosphate form.

Statistical methods. Comparisons of the effects of HSA relative to the effects of APS (Δ HSA/APS) on leukemic marrow cell proliferation and intracellular ara-C metabolism were analyzed using Student's *t* test and Fisher's exact *t* test. The relationships between HSA-induced changes in growth and pharmacologic parameters and clinical outcome (CR, NR) were also analyzed using Student's *t* test and Fisher's exact *t* test.

the individual AML marrow cell suspensions from the 45 NPT patients demonstrated similar and reproducible behavior among this population, regardless of clinical outcome (Table 1). The HSA-induced increase in cell proliferation was similar to that detected for normal hematopoietic populations in vitro[42] and was similar for the 31 CR and 14 NR patients. Significant increases in both parameters were detected for AML cells from both CR and NR patients cultured in HSA relative to cells maintained in the pretreatment milieu of APS by 18 hours of culture. The incorporation of $[^3H]$ ara-C into DNA by these AML populations demonstrated greater variability than the counterpart $[^3H]$dThd assay, similar to our findings for normal hematopoietic populations,[42] without consistently significant effects of HSA detected for all patients. However, the effect of HSA on the $[^3H]$ ara-C LI of cultured AML populations was similar to that noted for $[^3H]$dThd incorporation and LI, with significant increases detected in $[^3H]$ ara-C leukemic blast LI.

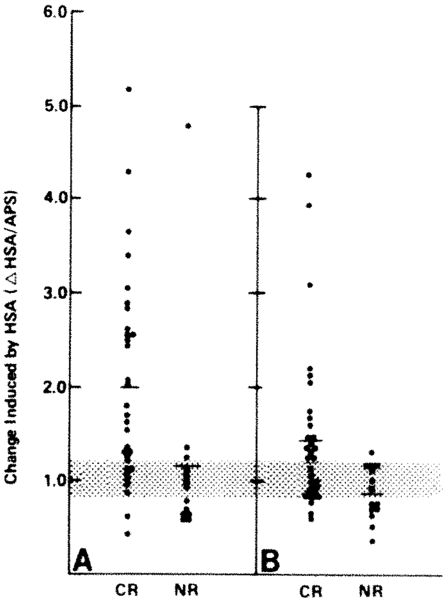

Fig 1. Effect of HSA on measurements of intracellular Ara-CTP retention relative to clinical outcome. The change induced by HSA relative to the effect of APS in (A) quantitative intracellular Ara-CTP retention (Δ R) and (B) relative retention (Δ R/F) is depicted for each of the individual 31 CR and 14 NR patients. Mean Δ R and Δ R/F for the CR and NR subgroups are depicted by horizontal bars. The shaded area represents Δ of 0.80 to 1.20; nonshaded areas represent significant induced changes for individual marrow populations.

Intracellular ara-C metabolism. The HSA-induced alterations in intracellular ara-C metabolism by cultured AML marrow cells demonstrated markedly different patterns for CR and NR patients (Tables 2 and 3, Fig 1). These differences, however, were detected only after an 18-hour exposure to HSA, when peak measured proliferation is detected.[38-43] Determinations of three-hour intracellular ara-CTP formation at the time of culture initiation (time 0) were similar for all marrow cell populations cultured in APS (CR, mean 6.1 pmol ara-CTP/10^6 cells, range 0.9 to 27; NR, mean 7.1 pmol/10^6 cells, range 1.1 to 24) and those cultured in HSA (CR, mean 7.6 pmol/10^6 cells, range 1.0 to 30; NR, mean 7.7 pmol/10^6 cells, range 1.0 to 22). Thus, similar to the findings of others,[8,9,12] we did not detect significant differences in baseline AML intracellular ara-C metabolism between CR and NR patients. Likewise, measurements of subsequent 1-hour intracellular ara-CTP retention and relative percentage of ara-CTP retained (R/F) in APS-cultured cells were similar for CR (mean retention 4.8 pmol/ 10^6 cells, range 0.6 to 19; mean R/F 70.5%, range 29 to 112) and NR (mean retention 4.3 pmol/10^6 cells, range 0.5 to 14; mean R/F 69%, range 36 to 101) subgroups. Cells from CR patients that were exposed to HSA during the initial three hours of culture tended to have greater intracellular ara-CTP retention (mean 5.8 pmol/10^6 cells, range 0.8 to 20; mean Δ HSA/APS 1.37, range 0.62 to 3.62, $P = 0.09$) and R/F (mean 82.6%, range 10 to 162; mean Δ HSA/APS 1.14, range 0.34 to 2.25, $P = 0.12$) than APS-cultured cells, while

§Δ HSA/APS, change induced by culture in HSA relative to maintenance in APS.

cells from NR patients demonstrated no such HSA-related trends in either retention (mean 4.9 pmol/10^6 cells, range 0.2 to 14) or R/F (mean 66.2%, range 10 to 90). Initial exposure to HSA resulted in modest increments in these pharmacologic measurements, particularly with respect to active drug retention by CR populations, but these HSA-related changes were not markedly different either from CR cells maintained in APS or from NR populations assayed during the initial phases of the culture period.

Following 18 hours in culture, however, the pharmacologic behavior of HSA-stimulated cells from CR patients was distinct from similarly cultured cells obtained from NR patients (Table 2, Fig 1). Significant increases in both three-hour intracellular ara-CTP formation ($P < 0.006$) and subsequent one-hour ara-CTP retention ($P < 0.002$) were detected for the 31 CR cell populations cultured in HSA relative to the same cells maintained in APS, with a greater HSA-related increase detected for retention than for formation ($P < 0.02$). In contrast, only modest HSA-induced enhancement of ara-CTP formation and no such enhancement of active drug retention was detected for cells from the 14 NR patients. Furthermore, although there was no significant difference in the absolute amounts of ara-CTP formed for CR and NR populations, the HSA-induced increase in ara-CTP retention by CR cells ($P < 0.01$) was significantly greater than that detected for NR cells. Parallel HSA-induced perturbations in growth kinetics and intracellular ara-C metabolism were associated with achievement of CR; conversely, divergence of cellular growth and pharmacologic behavior in the HSA-stimulated state was associated with clinical ara-C refractoriness (Table 3). The percent of relative intracellular ara-CTP retention (R/F) for cells from the 31 CR and 14 NR patients was similar when cells were maintained in APS for 18 hours and was similar to the same parameters obtained by immediate (time 0) exposure to ara-C in vitro. For the HSA-cultured CR populations, however, relative retention was magnified (Δ R/F, comparing R/F in HSA milieu with R/F in APS), unlike NR populations, with the percentage of ara-CTP retained by HSA-perturbed CR cells being greater than the percentage retained by HSA-cultured NR cells ($P < 0.01$).

DISCUSSION

These studies of human AML marrow cells examine the interrelationship between cell growth kinetics and intracellular biochemical pharmacology of the S-phase-specific antimetabolite ara-C. Measurements of these parameters are feasible and can be evaluated in at least 75% of our adult AML patient population. From our data we are able to identify behavior patterns of ara-C activation and net metabolism in the kinetically perturbed, proliferative state that may discriminate clinical sensitivity from clinical resistance to ara-C-based timed sequential therapy. The linkage of HSA-perturbed growth with HSA-enhanced intracellular drug disposition in clinically sensitive AML cohorts parallels our findings in normal human hematopoietic cells,[42] while clinically resistant leukemic populations demonstrate an uncoupling of proliferative and biochemical determinants in the growth-stimulated milieu. Such uncoupling likely signifies divergence from normal drug-sensitive behavior and, thus, resistance to ara-C cytotoxicity. These findings further provide a biochemical rationale to our observations regarding enhanced ara-C cytotoxic effects in HSA-stimulated populations and substantiate data derived from in vitro chemotherapy models in human hematopoietic cancers[33,43] as well as support our in vivo trials of timed sequential therapy in leukemia-bearing rodents[24,26,34,39] and in humans with acute leukemia.[31,35,36]

The in vitro effects of HSA were not immediately measurable either in terms of growth perturbation or enhanced net drug metabolism. This lag time with respect to both factors is not surprising given the mechanisms of action defined for the multiple hematopoietic stimulators.[39-41,45-47] HSA likely acts during G_1 and effects recruitment of target cells into S phase[24,32,39,41-43,45,46]; hypothetically its initial actions may relate to changes at the cell membrane level that affect nucleoside receptor number or binding and/or to induction of enzymes that promote intracellular nucleoside metabolism, ie, cytidine kinase, as well as enzymes such as thymidylate synthetase that facilitate DNA synthesis and eventually culminate in proliferation as measured by entry into S phase. The modest increments in pharmacologic parameters noted during the initial three to four hours of culture in HSA may reflect these postulated initial actions. The full effects of HSA perturbation, however, are realized only after an exposure time that allows for entry of those stimulated cell cohorts into S phase with ongoing DNA synthesis.

Our data demonstrate a differential effect of HSA on biochemical measurements of net intracellular ara-C metabolism by cultured AML populations with respect to eventual clinical outcome of ara-C-based timed sequential therapy. Although all HSA-perturbed populations evinced some increase in intracellular ara-CTP formation relative to APS-maintained cells, this enhancement tended to be greater in sensitive cohorts than in resistant cells. This enhancement may relate to changes induced at multiple potential sites where ara-C activity could be modulated, including membrane receptors and transport systems,[48] intracellular pool sizes of cytidine metabolites,[49,50] or enzymes responsible for ara-C activation.[4,14,51,52] However, the overall effect of HSA on this initial stage of intracellular ara-C metabolism does not clearly differentiate drug-sensitive from drug-resistant leukemic populations, suggesting that the underlying ara-C activation mechanisms affected by HSA are perhaps directly linked to mechanisms related to proliferation in both subgroups.

Determinations of quantitative and relative intracellular ara-CTP retention, as the measurement of net drug metabolism, in the growth-stimulated state appear to directly relate to eventual clinical outcome of ara-C-based timed sequential therapy. The HSA-related increase in activated ara-C retention measured in CR patients may well reflect an increased stability of triphosphorylated drug intracellularly. The paradoxical decrease in ara-CTP retention detected in growth-stimulated NR populations is less readily explained but may relate to increased levels of degradative enzymes or to efflux of active drug from the cell. Such potential defects cannot be determined from our data but are worth further consideration.

These data may further suggest a difference in both baseline and HSA-perturbed proliferation between CR and NR cell cohorts that could impact on pharmacologic behavior. Although all AML populations responded to HSA by increasing the proportion of cells in S phase and undergoing DNA synthesis, cells from NR patients tended to have modestly increased $[^3H]$dThd incorporation relative to cells from CR patients. The tendency for therapy-resistant cells from various hematologic malignancies to have higher initial DNA content and/or greater proportions of cells in apparent S phase has been detected by some investigators.[30,53,54] It is conceivable that some of our refractory AML cohorts may have an intrinsically shortened G_1 phase of the cell cycle that is further aggravated by exposure to HSA and during which the requisite processes leading to net drug activation, metabolism, and eventual incorporation into DNA cannot be carried to completion.

From our present studies we conclude that sensitive AML marrow cell populations behave similarly to normal hematopoietic cells[42] with direct linkage of growth and pharmacologic behavior that culminates in enhanced ara-C cytotoxicity in the HSA-perturbed nonsteady state, while refractory cells demonstrate uncoupling of these determinants. This in vitro model using HSA to partially overcome kinetic heterogeneity parallels timed sequential therapy, where initial drug priming induces proliferation of the residual tumor cohort in vivo[26,29,33,37,38] and supports the premise that such induced proliferation renders target cells more sensitive to the effects of an optimally timed ara-C infusion when those cells are capable of appropriate pharmacologic response. These in vitro measurements of interrelated growth and pharmacology may further serve as a template for prediction of clinical outcome to timed sequential therapy with ara-C, where both determinants of response are intrinsic to the designed drug scheduling.[24,29,31,35-37,39]

The Molecular Basis of β-Thalassemia in Lebanon: Application to Prenatal Diagnosis

By F.F. Chehab, V. Der Kaloustian, F.P. Khouri, S.S. Deeb, and Y.W. Kan

A study of the molecular lesions of β-thalassemia in Lebanon revealed the presence of eight different mutations in 25 patients with Cooley's anemia. The IVS1 position 110 mutation predominated with a frequency of 62% and was almost invariably associated with Mediterranean chromosome haplotype I. Five other mutations commonly found in the Mediterranean area occurred with frequencies of 2% to 8%. In addition a G → C substitution in IVS1 position 5 (a lesion previously found in Chinese and Asian Indians) was demonstrated in a patient with Mediterranean haplotype IX. A new mutation at codon 29 was found in two other patients with haplotype II. The characterization of these β-thalassemia mutations should allow the implementation of a prenatal diagnosis program in that country.

© 1987 by Grune & Stratton, Inc.

LEBANON, a small country on the Mediterranean Sea, is known to have interacted with many civilizations over the centuries, and the Lebanese population has resulted from an admixture of various ethnic groups. The incidence of β-thalassemia trait of both the β^0 and β^+ forms[1] is 2% to 3% in Lebanon.[2] Consanguineous marriages within certain ethnic communities having a high incidence of β-thalassemia have led to an increase in homozygous patients within that particular community. Clinically, homozygous β-thalassemia in Lebanon is manifested as the severe transfusion-dependent state, a form of Cooley's anemia that prevails in the Mediterranean region, throughout the Middle East, the Indian subcontinent, Burma, and southeast Asia.[3] The elucidation of the molecular defects of β-thalassemia in Lebanon should be informative on both scientific as well as anthropologic levels, since it would reflect the diversity of populations residing in that country. Whereas therapy for β-thalassemia has been mainly supportive, prevention of the disease by prenatal diagnosis has been a major goal in areas where the incidence is high. The characterization of the molecular defects would allow implementation of a prenatal diagnosis program. In this study, we have delineated the molecular lesions of β-thalassemia in Lebanon. We first studied the linkage of DNA polymorphisms in the β-globin gene cluster to specific β-thalassemia mutations and then defined specific mutations with oligonucleotide probes or by cloning and sequencing. We found eight different DNA haplotypes and eight different mutations among 50 β-thalassemia chromosomes. Six mutations were previously described in the Mediterranean population; one mutation previously found in the Chinese and Asian Indian populations was also found in this Mediterranean population on a new haplotype. In addition, we uncovered a new mutation that has not been previously described.

METHODS

Patients. Twenty-five unrelated homozygous β-thalassemic subjects (three β^0 and 22 β^+) were studied. All but one Christian patient were either Sunni or Shiite Moslems. Individuals in the present study have typical histories of transfusion-dependent Cooley's anemia.

DNA extraction and Southern blotting. DNA was extracted from the peripheral blood of affected individuals by either the proteinase K method[4] or by the standard procedure of phenol-chloroform extraction.[5] Ten micrograms of DNA were digested to completion with the appropriate restriction enzyme, separated according to size on agarose gels, transferred to nitrocellulose filters,[6] and hybridized to ^{32}P-nick translated β, γ, ψβ, and ε globin gene probes. DNA haplotypes were determined using seven common restriction site polymorphisms in the β-globin cluster.[7]

Oligonucleotide hybridization. Synthetic 19-mer oligonucleotide probes were labeled by phosphorylation of the 5′ ends with γ-^{32}P-ATP (7,000 Ci/mmol, ICN or New England Nuclear, Boston) and T4 polynucleotide kinase. The labeled oligonucleotide was then separated from unincorporated nucleotides by thin layer chromatography on diethyl aminoethyl (DEAE) cellulose plates (Analtech, Newark, DE) in the presence of urea and hydrolysed yeast tRNA.[8] Five to ten micrograms of genomic DNA were digested with Bam HI, separated on 0.8% agarose gels, and processed exactly as described,[9] except that the hybridization and washing temperatures were varied according to the probe used as shown in Table I. These temperatures were empirically selected according to the formula of Conner et al,[9] then experimentally adjusted.

Molecular cloning and DNA sequencing. One hundred fifty to two hundred micrograms of genomic DNA were completely digested with Eco RI or Hind III, fractionated on 10% to 40% sucrose gradients, and the β-globin-rich fraction identified by Southern blotting. Bacteriophage λ Charon 4A and Charon 30 were used for Eco RI and Hind III vectors, respectively. The recombinant bacteriophage clones containing β-globin inserts were generated as described.[10] Bacteriophage clones containing the 5.2 kb, 3.6 kb Eco RI fragments and 7.8 kb Hind III β-globin fragments were thus isolated. The 5.2 kb and 7.8 kb fragments were further subcloned in either of the bacterial plasmids pBR322, pUC18, or pBS (Stratagene Cloning Systems, San Diego). DNA sequencing of double-stranded supercoil DNA was essentially as described.[11]

Prenatal diagnosis. DNA from a Lebanese couple with a child affected by homozygous β-thalassemia was haplotyped for DNA polymorphisms in the β-globin cluster, and the most likely mutation

linked to this haplotype was identified by oligonucleotide hybridization. After obtaining informed consent from the parents, 35 mL of amniotic fluid was collected in Lebanon and flown to San Francisco within 24 hours. The packed cells were collected by centrifugation, washed, resuspended in 400 μL of 0.1 mol/L NaCl, 0.05 mol/L Tris HCl pH 7.5, 1 mmol/L EDTA, and lysed with 25 μL of 10% SDS. The lysate was digested overnight with 100 μg/mL proteinase K at 55°C, phenol was extracted, and ethanol was precipitated. Five micrograms of DNA were digested with Bam HI and were processed as described above for oligonucleotide hybridization.

RESULTS

Haplotypes. One Asian and seven common Mediterranean haplotypes were found in the Lebanese population. Table 2 lists the haplotypes detected and their frequencies. Mediterranean haplotype I predominated over the other haplotypes. Twenty-three of the 25 patients were homozygous for a single haplotype (I, II, III, IV, VI, VII, and IX) and two were doubly heterozygous for two different haplotypes (I/VI and II/Asian H).

Detection of mutations. To elucidate the molecular defects of β-thalassemia in this population, we tested each patient's DNA by either Southern blotting or oligonucleotide hybridization for one or more mutations previously shown to be linked to that haplotype. If the molecular lesions could not be uncovered according to the above strategy, the β-globin genes were cloned and sequenced.

Two mutations were detected by Southern blotting. Patients with haplotype III and haplotype VII were tested for the IVS2 position 1 (G → T) and IVS2 position 745 (C → G) lesions that respectively alter the Hph I and Rsa I restriction endonuclease sites. One patient each was found to be homozygous for these two mutations.

Synthetic oligonucleotide hybridization detected the mutation in 18 other patients who are homozygous for a single haplotype. These include the IVS1 position 110 mutation in 15 β-thalassemia patients homozygous for haplotype I, the IVS1 position 6 mutation in a patient homozygous for haplotype VI, the nonsense mutation at codon 39 in a homozygote for haplotype II, and the dinucleotide deletion at codon 8 in a homozygote for haplotype IV. In addition, a patient who is doubly heterozygous for haplotypes I and VI is also homozygous for the IVS1 position 6 mutation.

The molecular lesions in the β-globin genes from four other patients were not detected by the above strategy. The β-globin genes of a patient homozygous for haplotype IX were cloned in Charon 4A and subcloned in pBR322. Supercoil DNA sequencing showed that the mutation was a G → C substitution at IVS1 position 5 (Fig 1). This substitution was subsequently confirmed by oligonucleotide hybridization to be present on both of this patient's chromosomes (Fig 2).

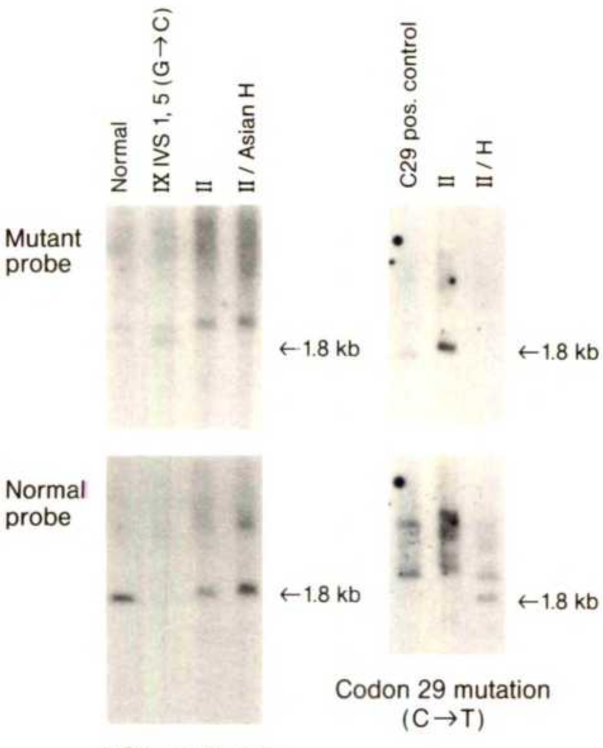
The second patient with an uncharacterized mutation was a double heterozygote for haplotypes II and Asian H. By oligonucleotide analysis, he carried the IVS1 position 110 lesion on one chromosome. His β-globin genes were cloned in Charon 4A followed by subcloning in pBS, and DNA sequencing revealed the IVS1 position 110 mutation on haplotype II. The other chromosome with the Asian H haplotype carried the dinucleotide deletion in codon 8, which has previously been reported to be associated with Mediterranean haplotype IV.

Two other patients homozygous for haplotype II failed to show any of the above mutations. The β-globin genes from one were cloned in Charon 30 and subcloned in pUC18. DNA sequencing revealed a base change (C → T) at codon 29 (Fig 1). Two oligonucleotide probes complementary to the normal and mutated sequence at codon 29 were then synthesized and hybridized to genomic DNA from these two

Table 2. Distribution of β-Thalassemia Haplotypes in Lebanon

Haplotype	ϵ	$^G\gamma$	$^A\gamma$	$\psi\beta$		β	$3'\beta$	Chrom	Frequency
I	+	−	−	−	−	+	+	31	0.62
II	−	+	+	−	+	+	+	7	0.14
III	−	+	−	+	+	+	−	2	0.04
IV	−	+	−	+	+	−	+	2	0.04
VI	−	+	+	−	−	−	+	3	0.06
VII	+	−	−	−	−	−	+	2	0.04
IX	−	+	−	−	+	−	+	2	0.04
Asian H	−	+	−	−	+	−	+	1	0.02

The polymorphic restriction sites were: The Hinc II site 5′ to the ϵ gene; the Hind III sites in the second IVS of the $^G\gamma$ and $^A\gamma$ genes; the two Hinc II sites in and 3′ to the $\psi\beta$ gene; the Ava II site in the β-gene and the Bam HI site 3′ to the β gene. (+) or (−) denote respectively the presence or the absence of the polymorphic site.



Codon 29 mutation (C→T)

IVS 1 position 5 (G→C)

Fig 1. Oligonucleotide hybridization of DNA from a normal patient and four patients in whom the mutations were not identified. In the left panels, oligo's 6 (see Table I) were hybridized to DNA from a normal individual, two patients homozygous for haplotypes IX and II, and one patient doubly heterozygous for haplotypes II and Asian H. Note that DNA from IX hybridized with the mutant probe, thus confirming the IVS1,5 (G → C) mutation. In the right panel, oligo's 6 were used. The first lane contains genomic DNA from a patient homozygous for haplotype II in which cloning and sequencing identified the codon 29 mutation and serves as a positive control. The second patient homozygous for haplotype II also hybridized with this probe. The patient with haplotype II/H did not hybridize with the mutant probe. The 1.8-kb fragments in which these two mutations reside are identified by the arrows. Other bands are due to cross-hybridizations.

patients. Both proved to be homozygous for the same substitution at codon 29 (Fig 2).

Thus in this sample of 50 β-thalassemia chromosomes from Lebanon, eight different mutations were found to account for β-thalassemia. Haplotype I and the IVS 1 position 110 lesion are strongly linked in this population and accounted for 60% of the β-thalassemia mutations. The other seven mutations are distributed at a frequency range of 2% to 8%. The heterogeneous β-thalassemia mutations in Lebanon can thus be detected by the use of six oligonucleotide probes and two restriction enzymes (Table 3).

Prenatal diagnosis. We have performed a prenatal diagnosis for a Lebanese fetus at risk for β-thalassemia by oligonucleotide hybridization of amniotic DNA. Previous screening of the parents and an affected child revealed that the β-thalassemia alleles were on chromosomes haplotype I, and hybridization with oligonucleotide probes showed that the mutation was the IVS1 position 110 (G → A). The fetal DNA when tested with oligonucleotide probes for this mutation hybridized only to the normal probe. Thus the fetus did not carry this mutant β-globin allele.

DISCUSSION

The clinical manifestation of β-thalassemia in Lebanon is severe, and homozygous patients have β/α globin synthetic ratios of 0 to 0.34.[1] In this study we have delineated the molecular defects in 25 transfusion-dependent β-thalassemia Lebanese patients by Southern blotting, synthetic oligonucleotide probing of genomic DNA, and molecular cloning followed by DNA sequencing. The Lebanese population carries eight different β-thalassemia mutations, six of which have been previously reported in the Mediterranean area. The IVS1 position 110, IVS1 position 6, IVS2 position 1, IVS2 position 745, β^{39} nonsense mutation, and frameshift mutation at codon 8 have all been shown to significantly alter the normal expression of the β-globin gene.[12-14] The linkage of β-thalassemia mutations in Lebanon to DNA haplotypes in the β-globin cluster was similar to that described[7] for haplotypes I, II, III, IV, VI, and VII. In addition we found four new linkages in this population: the mutation in IVS1 position 6 to haplotype I, the mutation at IVS1 position 5 (G → C) to haplotype IX, the dinucleotide deletion at codon 8 to the Asian H haplotype new to the Mediterranean, and the new mutation at codon 29 to haplotype II.

All of these mutations except the one at codon 29 have been previously described. The β^{39} mutation[13,14] has also been found in Sardinia,[15] Morocco, Algeria,[13] Greece, and Turkey.[16] The nucleotide substitution at the 5′ splice site of IVS2 has been described in an Italian and in some Iranian patients.[16] The dinucleotide deletion at codon 8 was originally detected in a Turkish patient.[7] The IVS1 position 110 mutation[17,18] is the most common cause of β-thalassemia in Mediterranean countries.[7]

The IVS1 position 6 mutation was originally found in a Portuguese patient[19] and subsequently in Greek Cypriots.[20] Typically the clinical course of patients with this mutation is mild in nature. However, the two Lebanese patients with this mutation have a more severe clinical disease as they both showed typical thalassemic facies, had β/α globin synthetic ratios of 0.34 and 0.20, and required regular blood transfusions when their hemoglobin levels fell below 6 to 8 g/dL. Although the reason for the more severe clinical course in the Lebanese patients is not known at this time, Lebanese parents at risk for this mutation should also receive genetic counseling for prenatal diagnosis.

The substitution (G → C) at IVS1 position 5 is interesting because it was previously found in the Chinese[21] and Asian Indian[22] populations. With its occurrence also in the Mediterranean region, it has now been found in three different populations. The fact that this mutation lies on a different haplotype in each population suggests that it arose independently in each and that this region of the β-globin gene is a hot spot for mutation.

The substitution at codon 29 was found in two patients, and while silent at the amino acid level, it creates a GT dinucleotide at this position 2 bp 5′ to the normal GT donor

splice site of IVS1. The new GT dinucleotide may act as a donor splice site, thus causing a frameshift. Alternatively, as in the case of hemoglobins E,[23] Knossos,[24] and a β-thalassemia found in a black patient,[25] this mutation may activate cryptic splice sites present in this region of the β-globin gene. We are currently investigating the precise splice point of the codon 29 mutation by DNA-mediated gene expression transfer experiments. Nevertheless, since the phenotype of this mutant is β^+, some normal splicing of this mRNA must remain.

Until recently, prenatal diagnosis of β-thalassemia using DNA analysis was usually performed by establishing linkage of polymorphic restriction sites along the β-globin cluster.[26,27] Currently synthetic oligonucleotide probes provide a more direct method for detecting the mutation in prenatal diagnosis.[9,28] The delineation of the molecular lesion would allow a rational approach to prenatal diagnosis in the Lebanese population. While haplotype I and the IVS1 position 110 mutation are predominant, parents and any affected children should be screened for specific β-thalassemia lesions and DNA polymorphisms in the β-globin cluster prior to an attempted pregnancy. This approach has been successful in the case reported herein.

The heterogeneity of β-thalassemia mutations in Lebanon may be explained by the history of this country, which has long been a crossroads of several civilizations. The ancient Phoenician culture has been well documented as a migratory civilization from Lebanon to various regions of the Mediterranean Sea and Africa and could have thus served as a genetic vehicle across populations contributing to the widespread nature of these mutations. Lebanon has witnessed the passage of many different populations in the last 500 years, from the Crusades to the Ottoman empire, and for the last 200 years has seen the convergence of various Moslem sects from neighboring Arab countries. This admixture of ethnicities may well be reflected by the genetic diversity of β-thalassemia mutations resulting from population migration and gene flow.

Table 3. Linkage of Haplotypes to β-Thalassemia Mutations in the Lebanese Population

Haplotype	Type	No. of Chrom	Mutation		Frequency	Detection
I	β^+	30	IVS1 position 110	(G → A)	0.60	Oligo 1
	β^+	1	IVS1 position 6	(T → C)	0.02	Oligo 2
II	β^0	2	Codon 39	(C → T)	0.04	Oligo 3
	β^+	4	Codon 29	(C → T)	0.08	Oligo 5*
	β^+	1	IVS1 position 110	(G → A)	0.02	Oligo 1
III	β^0	2	IVS2 position 1	(G → T)	0.04	Hph1
IV	β^0	2	Codon 8	(−2, AA)	0.04	Oligo 4
VI	β^+	3	IVS1 position 6	(T → C)	0.06	Oligo 2
VII	β^+	2	IVS2 position 745	(C → G)	0.04	Rsa I
IX	β^+	2	IVS1 position 5	(G → C)	0.04	Oligo 6*
Asian H	β^0	2	Codon 8	(−2, AA)	0.02	Oligo 4*

*These mutations were initially detected by cloning and sequencing.

Localization of Chlorotetracycline Fluorescence in Human Polymorphonuclear Neutrophils

By Thomas D. Coates, Martine Torres, Jon Harman, and Vicki Williams

Chlorotetracycline (CTC) has been used in many cells as a probe for membranous calcium. In polymorphonuclear neutrophils (PMN), the changes in CTC fluorescence upon stimulation are considered to monitor an early event in the activation process. Using quantitative video-enhanced microscopy, we report that in resting cells about 80% of the CTC signal emanates from the perinuclear region of the cell, indicating that internal structures are labeled with CTC. Approximately 20% of the total CTC fluorescence is taken up in a compartment sensitive to mitochondrial inhibitors, which is not present in neutrophils depleted of nucleus and granules or cytoplasts. Upon stimulation PMN loaded with CTC exhibit a rapid, biphasic decrease in fluorescence that is dose dependent. The second phase of the response is not seen in neutrophil cytoplasts. These results suggest that internal stores of CTC are responsive upon stimulation and could account for the later decrease in CTC fluorescence, whereas the early phase of CTC changes represents the plasma membrane response.
© 1987 by Grune & Stratton, Inc.

THE FLUORESCENT probe chlorotetracycline (CTC) has been employed in several cell systems to detect membrane-bound divalent cations.[1-4] Its fluorescence is enhanced in apolar regions and in the presence of calcium or magnesium.[3,5] The effects of calcium and magnesium can be distinguished on the basis of differences in excitation and emission spectra.[3,5-7] While CTC fluorescence correlates with the uptake of radiolabeled calcium in resting cells,[2,8] it may not accurately reflect calcium status in stimulated cells where divalent cations, membrane potential, and intracellular pH are changing simultaneously. Factors other than calcium may play a role in determining the ultimate magnitude of CTC fluorescence change[9]; however, it is clear that change in CTC fluorescence is one of the earliest events during the activation of polymorphonuclear neutrophils (PMN) by n-formyl-methionyl-leucyl-phenylalanine (FMLP).[4,10] Since CTC is lipophilic, it can partition in all membranes. To further understand the nature of the CTC fluorescence response, we studied the localization of CTC within intact PMN and PMN devoid of granules and nucleus (PMN cytoplasts [CP]). By using the CTC response in CP as a model for the plasma membrane-associated CTC change, we have dissected the biphasic CTC response curve in intact PMN into an internal and an external component.

MATERIALS AND METHODS

Reagents. Cytochalasin B (Sigma Chemical, St. Louis) was dissolved in dimethyl sulfoxide (DMSO) at 10 mg/mL and used at a final concentration of 5 μg/mL. Aliquots of stock solution of FMLP (Sigma Chemical, St Louis) were prepared at 10^{-4} mol/L in 1% DMSO and kept frozen. CTC (ICN, Cleveland) was prepared fresh daily at 50 μmol/L in the experimental buffer. A 40% stock solution of Ficoll (mol wt 70,000, Pharmacia Fine Chemicals, Uppsala, Sweden) was made in 0.025 mol/L Tris-HCL, pH 7.4 and was filtered into a sterile flask. The stock was further diluted to prepare the gradient in phosphate-buffered saline (PBS) with 5 mmol/L glucose, pH 7.4 (PBSG).[11,12]

Cell preparation. Heparinized venous blood was obtained from normal volunteers in accordance with the precepts established by the Helsinki Declaration and with the approval of the Human Experimentation Committee of Indiana University. PMN were isolated as previously described[11,13] by dextran sedimentation, followed by centrifugation through a Ficoll-Hypaque gradient. PMN were maintained in HEPES buffer until ready for use.

Cytoplasts preparation. PMN were resuspended in a 12.5% Ficoll solution and treated for five minutes at 37°C with 5 μg/mL cytochalasin B. The suspension was then layered on a discontinuous gradient (25%, 16%) whose components had been prewarmed at 37°C for three hours. Cytochalasin B was present throughout the gradient. The gradient was then centrifuged for 30 minutes at 81,000 g (middle of the tube) at a temperature close to 33°C. After centrifugation the enucleated PMN were collected at the interface between the 12.5% and 16% layers.[11,12] The purity of the cytoplasts preparation was monitored microscopically and enzymatically as described.[11] Their functional activity was tested by their ability to produce superoxide anion (O_2^-). Preparations that were not in the normal range for both enzyme content and O_2^- production were rejected.

Chlorotetracycline measurement. After preparation as described, cytoplasts (CP) or cytochalasin B-treated PMN were washed three times in normal saline and resuspended in HEPES buffer, pH 7.4 (10 mmol/L HEPES, 130 mmol/L NaCl, 10 mmol/L KCl, 0.5 mmol/L glucose, 0.75 mmol/L $CaCl_2$, and 0.5 mmol/L $MgCl_2$) at 5×10^7/mL. Two hundred microliters of 50 μmol/L CTC in 10 mmol/L HEPES buffer, pH 7.4, was added to 200 μL of either the CP or the PMN suspension, and the resulting mixture was allowed to incubate at room temperature in the dark for 20 minutes. An aliquot of this solution was transferred to a cuvette, and the basal fluorescence was monitored in a Perkin-Elmer model MPF-44B fluorescence spectrophotometer (Perkin-Elmer Corp, Instrument Division, Norwalk, CT) equipped with magnetic stirring and a thermostated cell holder. The final concentration of cells was 5×10^6/mL and that of CTC was 2.5 μmol/L. Excitation and

emission wavelengths were 386 nm and 544 nm, with slits of 10 nm and 15 nm respectively. Results are expressed as percent decrease of CTC fluorescence with respect to baseline: $F_t \times 100/F_0$, where F_0 is the fluorescence baseline and F_t is the fluorescence at time t. To study the early and late phases of the CTC response, the percent decrease in CTC fluorescence was measured 20 seconds and seven minutes after addition of the stimulus.

Chlorotetracycline uptake. The rate of uptake of CTC into PMN or CP was determined by exposure to a fixed concentration of CTC for varying periods of time. CTC (25 μmol/L) was placed in 0.9 mL of HEPES buffer containing 5 mmol/L glucose into 1-mL microcentrifuge tubes at room temperature. At t = 0, 100 μL of a suspension of PMN or CP at 5×10^7 cells/mL were added. The cells were centrifuged immediately or after fixed periods of time and then washed by gentle addition of buffer without CTC. After centrifugation the supernatant was decanted, and the cells were resuspended in 1 mL of buffer devoid of CTC. The suspension was then sonicated for 30 seconds. This procedure gave similar results as extraction of CTC with ethanol (data not shown). The total fluorescence of the suspension was then measured. For comparison of PMN and CP, the respective curves were normalized based on the fluorescence at 20 minutes.

Mitochondrial inhibitors. PMN or CP were treated for five minutes at room temperature with 1 mmol/L potassium cyanide (KCN), 1 mmol/L sodium azide (NaN_3), or 10 μmol/L Rotenone prior to performing the uptake experiments. NaCl or DMSO was used as a control.

Video microscopy. Microscopic observation of PMN was carried out in a chamber designed to allow easy exchange of bathing medium while cells are under observation.[14] The chamber was maintained at 37°C by means of an Air Curtain stage warmer. PMN at 1×10^6 cells/mL were placed in the chamber and allowed to adhere to the cover slip. The chamber was placed on the fluorescence microscope and the fluid was exchanged for buffer containing 50 μmol/L CTC and allowed to incubate for 20 minutes. Experiments were performed on a Leitz Orthoplan microscope with Ploem illuminator set up in epi-fluorescence mode using the UV filter set (ex 340 to 380 nm, dichroic mirror 430, em $>$ 510 nm). Viability of PMN chosen for observation was determined by presence of spreading and evidence of spontaneous movement. While there was some autofluorescence seen at these wavelengths, the fluorescence of CTC-loaded PMN was considerably greater than background autofluorescence. To reduce cell damage and photobleaching of CTC by the UV light, images were obtained with exposure to light for brief periods, usually less than five seconds.

Image analysis system. Fluorescence was recorded with a Dage-MTI model 66 silicon intensified target video camera (Dage-MTI, Michigan City, IN) connected to a Panasonic NV-8030 time lapse video tape recorder (VTR). Images were digitized from video tape using a DS-65 digitizer board (The MicroWorks, DelMar, CA) and an Apple II+ microcomputer (Apple Computer, Cupertino, CA). The software used in this system is described elsewhere.[15] The image analysis techniques used here for determination of integrated optical densities are standard.[16]

Localization. PMN are viewed on a video monitor using the freeze-frame mode of the VTR (Fig 1). The cell of interest was outlined on the monitor with a moving cursor. The area outlined was then digitized and mapped at four to one ratio to a color monitor. This results in a four times enlarged image with each range of intensity represented by a different color (Fig 2). By adjusting the ranges of intensity, it was possible to arrive at an assignment such that a particular color corresponded closely to a particular structure in the original image. This technique was possible only because CTC, and therefore the major source of fluorescence, was confined to discrete structures in the PMN. The intensity information from the image was stored as a grey scale histogram (Fig 3) used for integration and quantitation of the fluorescence. The regions in the image are identified by the computer on the histogram. Thus by summing the area under a particular region in the histogram, it is possible to determine the approximate fluorescence of that region.

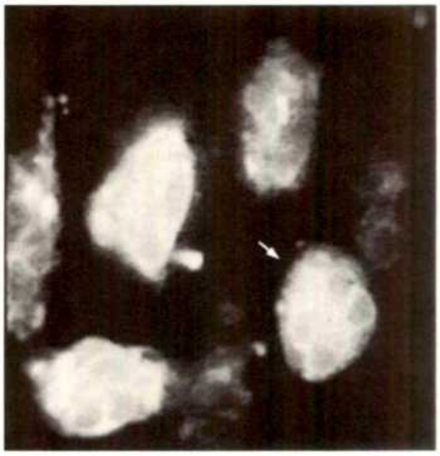

Fig 1. Video image of a group of PMN loaded with CTC. The image was photographed from the video monitor after recording on videotape. The cell indicated by an arrow corresponds to the cell digitized in Fig 2.

Data analysis. All data were analyzed using analysis of variance (ANOVA).

RESULTS

Video microscopy. When loaded with CTC, the fluorescence exhibited by PMN was not uniform. While present in all regions of the cell, the most intense fluorescence was seen in the perinuclear area between the lobes of the nucleus (Fig 1). One could observe discrete areas of bright fluorescence that moved and appeared to be attached to the nuclear membrane. These prominent fluorescent areas were adjacent to but not overlying the nucleus and thus represent CTC-stained membrane in the area between the lobes of the nucleus. Emanating from this same region were filamentous structures that fluoresced brightly with CTC (Fig 4). These areas were also brightly stained with the membrane potential probe rhodamine 123[17] (data not shown). When the cell formed a pseudopod, one or two of the filamentous structures could be seen moving out into the extended pseudopod and then retracting toward the center of the cell when the pseudopod retracted. These brightly fluorescent structures had clearly defined borders and were in the plane of focus of the nucleus. Some CTC fluorescence was present in a region that corresponds to the granules, as seen by transmitted light, and was located outside of the areas of focal fluorescence described above. When looking at CTC-loaded CP, which do not contain internal structures, a faint, uniform fluorescence was seen. Thus in PMN a significant part of the fluorescence emanates from membranous internal structures that were not present in CP.

Distribution of the fluorescence. When the frequency distribution of intensities from digitized PMN were examined, four regions could be identified (Fig 3). The brighter two regions corresponded to the areas of focal fluorescence,

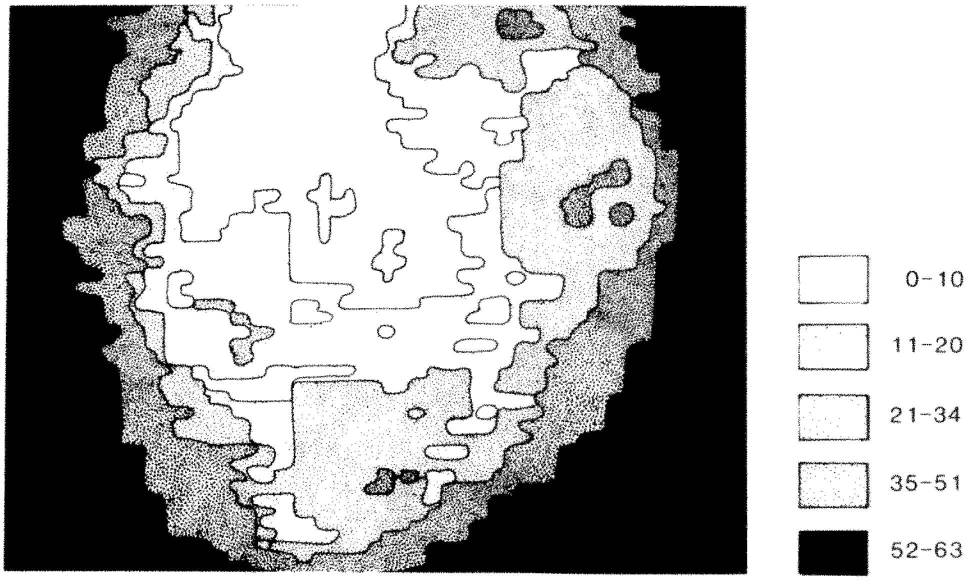

Fig 2. Intensity contour map of a cell from Fig 1. This map was produced from a pseudocolor representation. Note that 0 is the brightest and 63 is black. Region 0 to 10 is the perinuclear hot area, 11 to 20 the perinuclear membrane as well as dimmer areas of the perinuclear hot area, 21 to 34 a rough approximation of the area of the nucleus, and 35 to 51 the peripheral plasma membrane. Only part of the cell is seen because of the limitation of the display, but the digitization was done on the entire cell.

and the dimmer two regions to the area of the nucleus and of the plasma membrane. The percent of total fluorescence calculated from several cells by this method is shown in Table 1. Approximately 80% of the total cellular fluorescence came from the perinuclear area and nuclear membrane and occupied 60% of the image area. When corrected for the area of plasma membrane overlying the inner bright regions, plasma membrane fluorescence accounted for approximately 40% of the total cellular fluorescence. This is in agreement with the CTC baseline in suspensions of CP, which is 30% to 40% that of PMN at the same cell concentration.

Chlorotetracycline uptake. To assess possible differences in the compartmental distribution of CTC, the uptake of CTC was studied in similarly treated PMN and CP. Figure 5 shows the smooth uptake of CTC in CP achieving 50% of maximum by 60 seconds. In contrast, PMN demonstrated a biphasic pattern of uptake, reaching 50% maximum by approximately 10 seconds, followed by a slower rate from 60 to 1,200 seconds. The difference in pattern was highly significant ($P < 0.004$) when tested by analysis of variance. These data are consistent with the distribution of CTC in PMN in an additional compartment that is not present in CP.

Since CTC was localized in the same region as the mitochondrial probe Rhodamine 123, we investigated the effects of three inhibitors of mitochondrial function on the uptake of CTC. As demonstrated in Fig 6, KCN, Rotenone, and NaN_3 significantly inhibited the slow phase of CTC uptake ($P < 0.001$, 0.0001, and 0.007, respectively). When measured at 20 minutes, CTC fluorescence was inhibited by 24% with KCN, 21% with Rotenone, and 17% with NaN_3. Experiments were also carried out in CP that do not contain mitochondria.[18] Table 2 shows the CTC uptake after 20 minutes in CP treated with 1 mmol/L KCN or 1 mmol/L

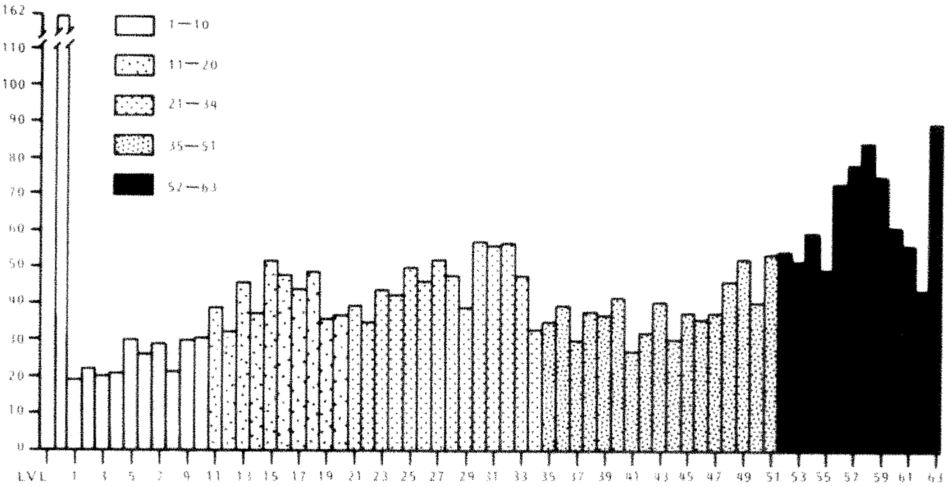

Fig 3. Video intensity histogram of the digitized cell in Fig 2. 0 is the brightest level and 63 the darkest level. The y axis represents the total number of points of a particular intensity in the image.

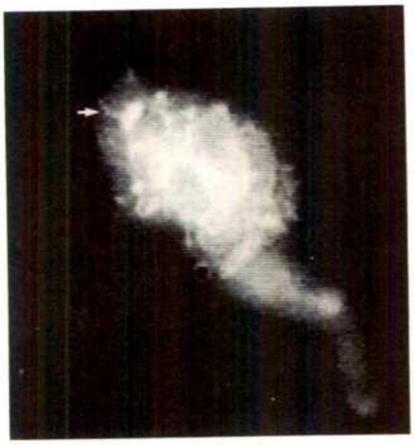

Fig 4. Image of a CTC-loaded neutrophil showing a bright filamentous structure (arrow).

NaN_3. There was no statistical difference in the amount of CTC uptake by CP ($P = 0.46$) in the presence or absence of these inhibitors. These data indicate that CTC uptake follows a distinctly different pattern in PMN and CP. Approximately 20% of the CTC is taken up into a compartment not present in CP that is sensitive to the mitochondrial inhibitors KCN, NaN_3, and Rotenone. While we cannot provide direct evidence that the CTC is in the endoplasmic reticulum and/or in the Golgi, 60% of the total fluorescence is in a nonmitochondrial inhibitor-sensitive, nonplasma membrane pool that is located in the perinuclear area of the cell.

Early and late responses in PMN and CP. The temporal pattern of fluorescence change in CP after stimulation with FMLP differs from that seen in intact PMN. Representative CTC fluorescence traces demonstrating these two patterns are shown in Fig 7. In PMN there was a rapid decrease in fluorescence during the first 20 seconds after stimulation, followed by a slower and more extensive loss of fluorescence. The second phase did not occur in PMN at doses less than or equal to 10^{-8} mol/L or at any dose in CP. Recovery was seen at low doses of stimulus and was not affected by the presence of CTC in the medium. Changes in fluorescence were measured 20 seconds and seven minutes from the time of addition of the stimulus to characterize the early and late responses when the cells were stimulated with increasing doses of FMLP. The early change in fluorescence was present in CP and did not significantly differ from that seen in PMN. There was no dose response in CP ($P < 0.19$), whereas a small but significant dose response was present in PMN ($P < 0.05$) (Fig 8A). When the late response was measured at seven minutes from stimulation, there was no further decrease in fluorescence in CP with no dose effect ($P < 0.03$) when a dramatic decrease was seen in PMN at seven minutes ($P < .0001$) (Fig 8B). This was not related to release of CTC in the external medium during degranulation, as no increase in CTC could be measured in the supernatant (data not shown). The secondary response was seen at doses of FMLP above 10^{-8} mol/L, similar to those usually associated with a secretory response.[19] These results imply that there is a second pool of CTC fluorescence, not

present in CP, that is released later after addition of stimulus at doses of FMLP greater than 10^{-8} mol/L.

DISCUSSION

Initial work using CTC fluorescence suggested that it represents a membrane-bound pool of calcium.[3,4,20,21] Change in fluorescence upon cell stimulation was interpreted as the release of trigger calcium[3,19]; however, the membranes labeled with CTC were not clearly defined. Direct visualization of CTC-labeled PMN presented here and by others[1,22,23] demonstrates that the fluorescence is located in the plasma membrane as well as in the perinuclear region of the cell, suggesting the existence of several membrane pools of CTC. Further evidence is given by the absence of internal focal fluorescence in PMN depleted of internal organelles and by the observation that in suspension PMN and CP have distinct patterns of uptake of CTC. Thus the compartmentalization of CTC observed microscopically exists in suspension and does not seem to be an artifact of adherence to glass slides.

The pattern of internal localization of CTC in PMN is consistent with the presence of calcium in mitochondria[24-26] and endoplasmic reticulum[8] as seen in other cell types. Mitochondria stained with CTC, as reported by others,[25,26] but only 20% of the CTC is present in this compartment. While mitochondria may play a role in the regulation of cytosolic calcium in PMN, the intracellular calcium concentration in PMN is more consistent with an endoplasmic reticulum-regulated calcium set point than with a mitochondria-regulated set point.[27] There is indirect evidence that the trigger calcium in PMN is located in an internal microsomal

Table 2. CTC Uptake in Cytoplasts

KCN	104.5	8	NS

Uptake of CTC in PMN cytoplasts after 20 minutes in the presence of 1 mmol/L KCN or 1 mmol/L NaN_3. The results are expressed as percent of control and are derived from the means of triplicates of five experiments.

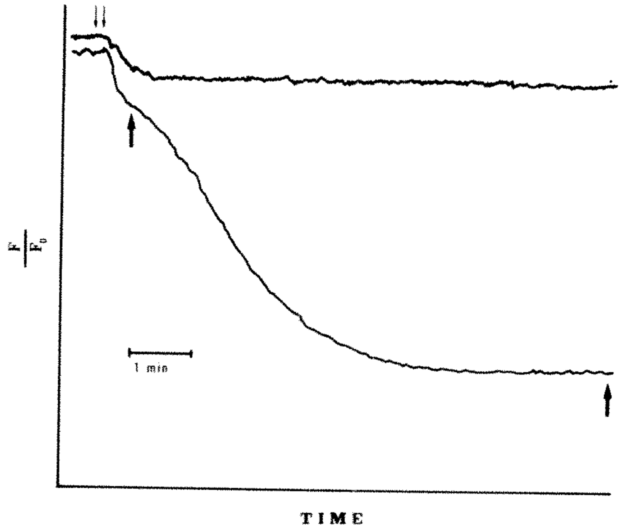

Fig 7. This tracing is representative of one experiment and shows the change in CTC fluorescence in PMN cytoplasts (top trace) and in PMN (bottom trace) when stimulated with 10^{-7} M FMLP (↓↓). Arrows indicate the times used for analysis in Fig 8 (↑).

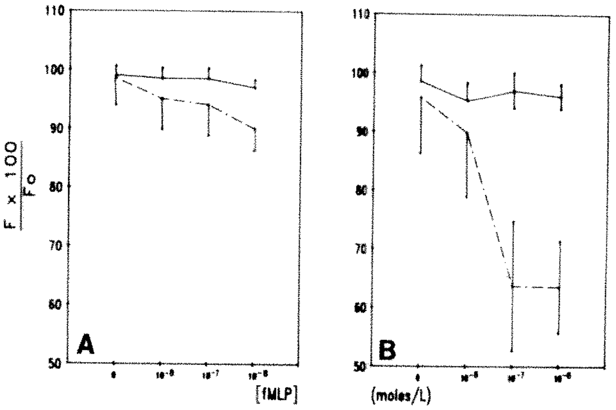

Fig 8. (A) demonstrates the CTC response 20 seconds from stimulation. There is no significant decrease in CP (———; P , 0.19), but the change in PMN is significant (-- --; $P < 0.05$). At seven minutes (B) there is still no dose effect in CP (———; $P = 0.3$); however, a significant effect is seen in PMN (-- --; $P < 0.0001$). Error bars represent the upper and lower 95% confidence intervals.

pool that is sensitive to inhibitors of the endoplasmic reticulum calcium pump.[27] The location of Golgi and endoplasmic reticulum in PMN corresponds spatially to the distribution of CTC seen in fluorescence microscopy. In other cell types the regions of perinuclear CTC fluorescence have been directly identified as Golgi and as endoplasmic reticulum.[23] Lysosomal granules represent another possible pool of intracellular calcium.[28] While some fluorescence comes from the granule membranes, the areas of maximum fluorescence are more centrally located. This is in agreement with another study using chicken PMN with large and more visible granulations.[22] These data support the hypothesis that a significant part of the CTC fluorescence in human PMN comes from internal pools.

Using CP as a model for neutrophil plasma membrane, the CTC response of intact PMN and of CP were investigated to determine if the internal pools of CTC were responsive upon stimulation with FMLP. Others have suggested that the major source of fluorescence loss is from the plasma membrane. Because of the technique used for microscopically studying the effect of stimulation, the earliest changes seen with soluble stimuli were observed at 60 seconds.[22] In suspension the early response is complete by this time, and the second phase of response is almost maximal. When the effects of stimulation are analyzed in suspension, there is little if any further response in CP at doses of FMLP greater than 10^{-8} mol/L, whereas in PMN there is a further phase of fluorescence loss. The biphasic CTC response seen in intact cells suggests that internal sources of CTC fluorescence, not available in CP, are responding to stimulation. The rate and dose dependency of the early response is similar in PMN and in CP and may be interpreted as change in the plasma membrane pool of CTC. The secondary response, which does not occur in CP, represents the CTC signal from internal sources.

ACKNOWLEDGMENT

The authors wish to thank Dr Robert Baehner and Dr Jesse Siskin for their help and encouragement during the early phases of this work, George Boder of the Eli Lilly Research Laboratory, Indianapolis, for the use of his equipment, and Jean-Paul Dervaux for his excellent secretarial assistance.

A Component of Factor VIII Preparations Which Can Be Separated From Factor VIII Activity Down Modulates Human Monocyte Functions

By Martha M. Eibl, Rafi Ahmad, Hermann M. Wolf, Yendra Linnau, Elisabeth Götz, and Josef W. Mannhalter

In this study we investigated different aspects of monocyte functions following interaction of monocytes (Mo) with therapeutic concentrations of factor VIII (F VIII) concentrate. A short (one-hour) treatment of normal Mo with F VIII concentrates led to a significant ($P < 0.001$) down modulation of Fc receptors expressed in the Mo plasma membrane. This down modulation was accompanied by a decrease of Mo effector functions that was expressed by a reduced capacity of F VIII-treated Mo to release O_2 radicals (40% of controls) and to kill bacteria (% killing: control Mo, 65%; F VIII-treated Mo, 24% to 51%). Further studies showed that the modulating activity was due to a contaminant present in F VIII concentrates (immune complexes or IgG aggregates). Fractionation using molecular sieving revealed that the modulatory activity was confined to a high-molecular range fraction (Mr > 1,270,000 daltons), while the fraction containing monomeric IgG had no effect. Further fractionation by affinity chromatography on protein A-Sepharose separated the coagulation activity (effluent) from the Mo function-modulating activity (eluate). We conclude that treatment with F VIII concentrates might contribute to an immunocompromised state in some hemophiliacs and facilitate opportunistic infections in these patients.

© 1987 by Grune & Stratton, Inc.

SEROLOGIC surveys of hemophiliacs revealed a high prevalence of HTLV III/LAV antibodies in this patient population (70% and more of hemophiliacs in the United States and Europe are anti-HTLV III-positive).[1-3] It is generally understood that these patients develop antibodies in response to retrovirus transmitted by the respective blood products used for therapy.[4-8] However, the course of an infection is usually determined by both the infectious dose and the host's defense mechanisms. Thus an impairment of host defense mechanisms might constitute an additional risk factor and render the respective individual more susceptible to infections.

The macrophage/monocyte system is known to play a major role in the elimination of microbial agents. Recent experiments have shown that an impairment of macrophage functions (induced by silica, a substance known to be toxic to macrophages) increases the susceptibility of cats to feline leukemia virus, a retrovirus.[9] Furthermore, retrovirus particles have also been detected in monocytes of patients with acquired immunodeficiency syndrome (AIDS).[10] These data motivated us to evaluate monocyte functions following interaction of monocytes (Mo) with factor VIII (F VIII) concentrate.

In the present study we have investigated whether and to what extent treatment of Mo with F VIII concentrates affects Mo functions. We report that F VIII concentrates had the capacity to down modulate Mo functions, including expression of Fc receptors, generation of oxygen radicals, and intracellular killing of microorganisms. We were able to identify a contaminant in F VIII concentrate preparations as being responsible for the observed effects.

MATERIALS AND METHODS

Factor VIII concentrates. Lyophilized factor VIII (F VIII) concentrates (Kryobulin M, lot # 09M09083, Immuno AG, Vienna, Austria) were dissolved according to the instructions on the enclosed package insert (10 mL distilled water per 250 IU F VIII) and adjusted to the appropriate concentration in RPMI 1640 medium (Flow Laboratories, Irvine, England) supplemented with L-glutamine (2 mmol/L) and antibiotics (100 IU/mL penicillin, 100 μg/mL streptomycin). Further definition of the F VIII concentrate used is given in Table 1.

Fractionation of F VIII concentrates. Fractionation of F VIII concentrates was first performed according to molecular size using gel chromatography. A Biogel A-1.5 M (Bio-Rad Laboratories, Richmond, CA) column (100 to 200 mesh, column size 2.6 × 95 cm) was loaded with 5 mL (89.2 IU) of F VIII and eluted at a flow rate of 27 mL/hour (elution buffer 0.024 mol/L sodium citrate, 0.12 mol/L sodium chloride, pH 7.2). This fractionation yielded five peaks with virtually all the F VIII activity confined to peak 1. The protein-containing fractions from peaks 1 to 5 were pooled, transferred into dialysis tubings (20 DM-X100 FT, Union Carbide, Chicago), and concentrated by embedding into polyethylene glycol 20,000 (Serva, Heidelberg, FRG) to an F VIII activity of 2 IU/mL in fraction 1. The volumes of fractions 2 to 5 were reduced to the same extent. The protein content of each fraction is shown in Table 2.

A part of fraction 1 (Mr > 1,270,000) was further subjected to affinity chromatography on protein A-Sepharose (protein A-Sepharose CL-4B, Pharmacia, Uppsala, Sweden; column size 1.6 × 4.5 cm, starting buffer 0.024 mol/L sodium citrate, 0.12 mol/L sodium chloride, pH 7.2; elution buffer 0.05 mol/L sodium citrate, 0.05 mol/L citric acid, pH 3.0; flow rate 28 mL/hour). The fractions eluting from the protein A-Sepharose column were immediately neutralized using 1 mol/L NaOH. The protein-containing fractions from both the protein A-Sepharose effluent and eluate were pooled and concentrated as described above.

Prior to use in cell culture experiments, all F VIII fractions were extensively dialyzed against Dulbecco's phosphate-buffered saline (PBS) without Ca^{2+} and Mg^{2+}. For monocyte pretreatment studies, Ca^{2+} and Mg^{2+} ions were added immediately before the incubation step.

Poly IgG. Human serum IgG (Cohn fraction II, a kind gift from Immuno AG) was dissolved at a concentration of 10 mg/mL in Dulbecco's PBS containing Ca^{2+} and Mg^{2+} ions (Flow Laboratories) and polymerized by heat aggregation at 63°C for 20 minutes.[12] To remove large aggregates the preparation was then centrifuged at 600 × g for ten minutes.

†IU/ml.

Isolation of mononuclear cells and preparation of monocyte monolayers. Mononuclear cells (MNC) were isolated from the peripheral blood of healthy human volunteers by buoyant density gradient centrifugation.[13] Anticoagulated blood (40 IU preservative-free heparin [Immuno AG, Vienna, Austria] per mL) was layered on Lymphoprep (Nyegaard & Co, Oslo, Norway) and centrifuged at 400 × g for 35 minutes. Then the mononuclear cells from the interphase were aspirated, washed three times in 0.15 mol/L NaCl, and suspended in RPMI 1640 supplemented with 15% pooled, heat-inactivated (30 minutes, 56°C) human AB serum, penicillin (100 IU/mL), streptomycin (100 μg/mL), and L-glutamine (2 mmol/L) (complete medium).

Monocytes (Mo) were prepared by adherence to plastic surfaces. MNC were suspended in complete medium at a concentration of 1×10^7 cells/mL. Two-milliliter portions thereof were pipetted into plastic tissue culture plates (Macro Tray 635 TC, Greiner & Söhne, Kremsmünster, Austria) and incubated at 37°C in a CO_2 incubator (5% CO_2 in humidified air) for 3 hours. At the end of the incubation period, nonadherent cells were removed, and the Mo monolayers were washed three times with 0.15 mol/L NaCl. Then complete medium was added, and the Mo monolayers were kept overnight at 37°C in a humidified CO_2 atmosphere. Adherent cells prepared in this way contained more than 90% Mo, as judged by nonspecific esterase staining.[14]

Pretreatment of Mo monolayers. Mo pretreatment was performed by incubating Mo monolayers with F VIII, F VIII fractions, or polymeric IgG for one hour at 37°C immediately after adherence. The F VIII concentrates were used at concentrations of 2 IU/mL, 5 IU/mL, and 10 IU/mL; protein concentrations of the respective F VIII fractions are shown in Table 2; polymeric IgG was applied at a protein concentration of 10 mg/mL. Mo pretreatment with buffer solutions (RPMI 1640 supplemented with L-glutamine and antibiotics and/or PBS containing Ca^{2+} and Mg^{2+} ions) was always included as a control. At the end of the 1-hour incubation step, the substances used for pretreatment were aspirated, and the Mo monolayers were washed with 0.15 mol/L NaCl and kept in complete medium at 37°C (CO_2 incubator) for 16 hours.

Determination of Fc receptors. Receptors for the Fc portion of IgG on the Mo membrane were determined by rosette formation with antibody-coated ox red blood cells.[15] Ox red blood cells were first sensitized with IgG by incubating equal volumes of ox red blood cells (2% suspension in PBS) and rabbit anti-ox red blood cell antibodies (IgG fraction, 0.167 mg/mL PBS, Nordic Immunology, Tilburg, The Netherlands) at 37°C for one hour.[16] Mo monolayers were washed twice with PBS containing 0.2% bovine serum albumin. Then the cells were gently scraped off with a rubber policeman and adjusted to 2 to 3×10^6 cells per mL. One hundred microliters of this cell suspension was mixed with 100 μL of a 0.5% suspension of IgG-sensitized red cells and centrifuged at 120 × g for ten minutes at 4°C. After 1 hour of incubation in an ice bath, the pellet was gently resuspended and the cells were examined by phase contrast microscopy. A minimum of 200 cells was counted, and a cell having three or more red cells attached was scored as a rosette. Results are expressed as percent rosette-forming cells (% RFC) or as attachment index (ie, the average number of red cells attached per Mo). The attachment index (AI) has been estimated by including all monocytes with none, one, or more than one erythrocyte attached and is calculated according to the following formula: AI = total number of red cells attached to 200 Mo divided by 200.

For competitive inhibition of rosette formation, 50 μL of Mo (6×10^6 Mo/mL) and 50 μL of IgG-sensitized red cells (1% suspension) were mixed with 100 μL of F VIII (2 IU/mL) or polymeric IgG (10 mg/mL) and treated as described above.

Determination of CR3. Expression of the complement receptor CR3 on monocytes was assessed by indirect immunofluorescence. Indirect immunofluorescence was carried out by first incubating (30 minutes, 4°C) 5×10^5 monocytes in 70 μL wash medium (Dulbecco's PBS containing 0.1% NaN_3 and 2% fetal calf serum) with saturating amounts of the monoclonal antibody (MoAb) Mol (94 ed, kindly provided by Dr R.F. Todd), which is directed against the iC3b receptor (CR3) on monocytes, granulocytes, and null cells.[17,18] After the first 30-minute incubation period, the cells were washed and again incubated for 30 minutes at 4°C in wash medium containing an excess of fluorescein isothiocyanate-conjugated goat antimouse immunoglobulin (GAM-FITC, Coulter Immunology, Hialeah, FL). After a further wash step, flow cytometric analysis of monocyte cell-surface fluorescence was performed by using a FACS 440 cell sorter equipped with an argon ion laser operated at 488 nm and 270 mW and interfaced to a Consort 30 computer (Becton Dickinson, Mountain View, CA). Contaminating lymphocytes were excluded by preselecting a gate on the forward-angle light scatter *v* the

right-angle light scatter histogram; dead cells were excluded by their bright red fluorescence after ethidium bromide staining. A minimum of 10,000 cells was counted and the percentage of fluorescent-positive monocytes stained with the experimental antibody (Mol) minus the percentage of cells stained with a control reagent (mouse ascites containing antibodies directed against nonhuman tissue) was calculated.

Assays of monocyte effector functions (chemiluminescence and killing). Monocyte monolayers were washed twice with 0.15 mol/L NaCl. Then the adherent cells were gently scraped off with a rubber policeman and adjusted to 1 × 10^6 Mo/mL in Hanks' balanced salt solution (HBSS; for chemiluminescence) or HBSS supplemented with 1% gelatine (for killing assays).

Chemiluminescence of monocytes was determined according to the method of Trush et al.[19] In brief, 1 × 10^5 monocytes were pipetted into a plastic cuvette (Luma Cuvette, 3M, St Paul) and mixed with luminol (Lumanol-1000, Lumac, Medical Products Division/3M, St Paul) to give a final concentration of 63 μmol/L per cuvette. Then opsonized zymosan particles (Zymosan A, Sigma Chemical, St. Louis; opsonized by incubation in the presence of fresh serum [30 minutes, 37°C, shaking water bath]; 0.237 mg/cuvette) or an outdated intramuscular IgG preparation containing IgG aggregates (1 mg/cuvette) was added. The total volume per cuvette was 0.4 mL; all substances were diluted or suspended in chemiluminescence buffer (MEM-Dulbecco for chemiluminescence, Boehringer-Mannheim G.m.b.H., Mannheim, FRG). The resulting chemiluminescence was measured in a bioluminescence counter (Biolumat LB 9505, Berthold, Wildbad, FRG). The results of chemiluminescence intensity were plotted as counts per minute *v* time.

The capacity of monocytes to kill bacteria was assessed by a modification of a procedure originally described by Quie and coworkers.[20] Monocytes (1 × 10^5 in 100 μL) were pipetted into flat-bottomed microtiter plates (Microtest II, Falcon, Oxnard, CA) and mixed with *Escherichia coli* 089:H10 (monocytes to bacteria ratio = 2:1). Fresh AB serum (antibodies and complement)—essential for adequate opsonization—was added to give a total volume of 200 μL per microtiter well and a final serum concentration of 1:25. This suspension was incubated with continuous agitation for 90 minutes at 37°C. Incubation of bacteria in the presence of monocytes plus fresh AB serum absorbed with *E coli* to remove anti-*E coli* antibodies was used as a control. At the end of the incubation period the monocytes were lysed with distilled water, and the number of viable bacteria was determined by a plate-pouring technique. The number of bacterial colonies per plate was determined by using a colony counter (Biotran, New Brunswick Scientific Inc, Edison, NY).

Results are presented as the number of bacteria per plate ± SEM and as percentage of bacteria killed. This percentage was calculated according to the following procedure: the mean number of bacteria surviving in experimental wells was subtracted from the mean number of bacteria surviving in control wells. The difference was then divided by the mean number of bacteria surviving in control wells and multiplied by 100.[21] Control wells contained bacteria plus monocytes plus fresh serum depleted of anti-*E coli* antibodies; experimental wells contained bacteria plus monocytes plus fresh serum.

Statistics. Statistical evaluation of all results was performed using Student's *t* test or Student's *t* test for paired samples.

RESULTS

F VIII concentrate preparations have the capacity to down modulate Fc receptor expression on Mo from healthy subjects. The data from Fig 1 show that F VIII concentrates had the capacity to decrease the number of Fc receptors expressed on the surface membrane of the monocytes of healthy subjects (down modulation of the Fc receptor). Pretreatment of monocytes with F VIII concentrate preparations in concentrations within the therapeutic range led to a significant ($P < 0.001$) reduction in Fc receptor expression as assessed by both the decreased percentage of Mo forming rosettes with IgG-coated ox red blood cells (% RFC) and the reduction in the average number of IgG-coated ox red blood cells attached per monocyte (attachment index). The F VIII-mediated down modulation of Fc receptor expression was comparable to that obtained after pretreating Mo with polymeric (heat-aggregated) IgG, a substance known to down modulate Fc receptors[22] (controls [pretreatment with buffer]: % RFC 81 ± 1, attachment index 3.92 ± 0.16; pretreatment of Mo with F VIII [2 IU/mL]: % RFC 40 ± 1, attachment index 1.85 ± 0.09; pretreatment of Mo with polymeric IgG: % RFC 34 ± 3, attachment index 1.46 ± 0.16; results represent $\bar{x}$ ± SD of ten experiments). Fc receptor down modulation was further supported by the frequency distribution curve shown in Fig 2. The number of IgG-coated red cells attached per F VIII-

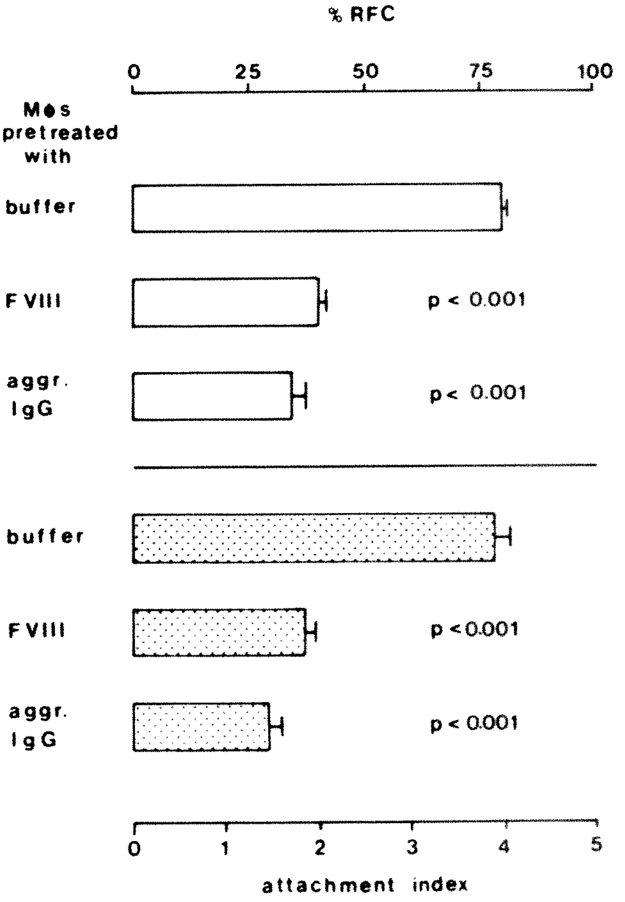

Fig 1. F VIII concentrates have the capacity to down modulate Fc receptor expression on normal monocytes. Normal Mo were incubated in the presence of buffer, F VIII (2 IU/mL), or polymeric IgG (aggr. 10 mg/mL) for one hour 16 hours prior to determination of Fc receptors. Each bar represents the percentage of Mo forming rosettes with antibody-coated red cells (% RFC) or the average number of red cells attached per Mo (attachment index).

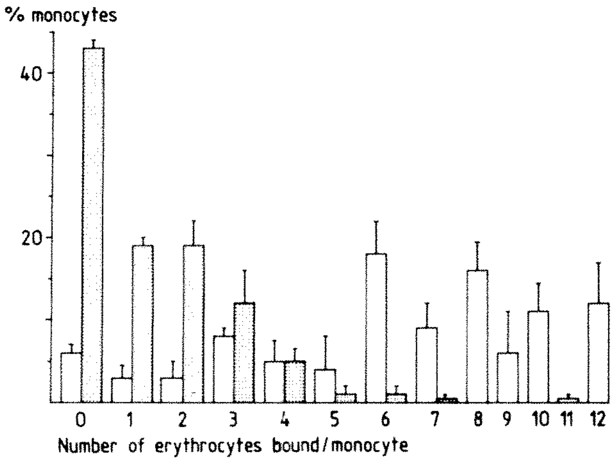

Fig 2. F VIII pretreatment of human monocytes leads to a reduction in the number of IgG-coated erythrocytes bound per monocyte. Human monocytes were pretreated for one hour with F VIII (2 IU/mL, dotted bars) or buffer (blank bars). After 16 hours FcR expression was assessed using IgG-coated ox red blood cells. The number of IgG-sensitized erythrocytes bound per monocyte was determined by phase contrast microscopy ($\bar{x} \pm$ SD of four experiments).

treated monocyte was substantially decreased as compared to the controls.

The decrease in Fc-receptor-positive Mo was achieved by both competitive inhibition of rosette formation (by adding F VIII to Mo together with IgG-coated red cells) and down modulation of the Fc receptor (by incubating Mo monolayers with F VIII for one hour 16 hours prior to rosette formation; Table 3). Our finding that sequential treatment of Mo with polymeric IgG and F VIII and vice versa did not further decrease the percentage of RFC or the attachment index (Table 4) strongly suggested that F VIII concentrates and polymeric IgG down modulated the same type of Fc receptor.

The reduction in the number of Fc-receptor-positive Mo could not be attributed to trivial cytotoxicity, since neither pretreatment with F VIII nor with polymeric IgG decreased the Mo's viability by more than 10%. Furthermore, the decreased expression of Fc receptors does not appear to be due to a blockade of the receptor by F VIII or by polymeric IgG. Studies using radioactively labeled immunoglobulins clearly demonstrated that after a 16-hour incubation period in the absence of IgG polymers, only minute amounts of polymeric IgG were found to be still monocyte-associated.[23] This 16-hour incubation period was always part of the Fc receptor-modulation protocol. Finally, a possible effect of buffer components present in lyophilized F VIII preparations was ruled out. Pretreatment of Mo with F VIII buffer (ie, buffer containing the same salt and amino acid concentrations as present in F VIII preparations after reconstitution of the lyophilized product with distilled water: 0.034 mol/L sodium citrate, 0.137 mol/L sodium chloride, 0.266 mol/L glycine) at a dilution corresponding to 2 IU of F VIII/mL did not alter the percentage of Fc-receptor-positive cells (control 84 ± 5.7, F VIII buffer 77 ± 6.6, F VIII [2 IU/mL] 51 ± 3.4; $\bar{x} \pm$ SD of four experiments).

The F VIII concentrates and the respective buffer solutions used in this study were provided by Immuno AG, Vienna, Austria. Similar results with respect to down modulation of Fc receptors could also be obtained by using F VIII concentrates of varying purity (1.3 IU to 12 IU per mg protein) from several other manufacturers. Furthermore, no difference between heat-treated and non-heat-treated F VIII preparations could be observed (M.M. Eibl et al, manuscript submitted).

The Fc receptor-modulating component in F VIII concentrates can be separated from F VIII activity. The above mentioned data (F VIII-induced competitive inhibition of rosette formation and down modulation of Fc receptors

comparable to the effects of polymeric IgG) already indicated the presence of a contaminating substance (immune complexes or IgG aggregates) in F VIII concentrate preparations. However, the possibility that the observed effects were due to steric hindrance of Fc receptors by F VIII binding to the monocytes could not be ruled out. Therefore F VIII concentrate preparations were subjected to fractionation. Molecular sieving using a Biogel A-1.5 M column yielded five protein peaks, and as the results from Table 2 show, the Fc receptor modulatory activity was confined exclusively to the high Mr fraction (Mr > 1,270,000 daltons). This fraction also included virtually all of the preparation's F VIII activity. None of the other fractions containing fibrinogen, monomeric IgG, or albumin had any effect on Fc receptor expression. The high Mr fraction of F VIII concentrate was then further fractionated by affinity chromatography on protein A-Sepharose, a substance known to interact with the Fc portions of human IgG_1, IgG_2, and IgG_4.[24] The data presented in Table 5 clearly demonstrate that only the fraction that could be adsorbed to immobilized protein A had the capacity to down modulate Mo Fc receptors (see Table 5, line 5). This fraction was also found to be completely devoid of F VIII activity. The fraction not adsorbed to immobilized protein A contained all the F VIII activity and had no Fc receptor-modulatory properties. Rough assessment using the F VIII preparation's total protein and IgG content as well as the protein concentration of the fraction bound to and eluted from immobilized protein A (protein A-Sepharose) indicates that about 1.9% of the total IgG in the F VIII concentrate used in this study was present in an aggregated and/or complexed form. Further results to be published elsewhere, however, demonstrate that the down-modulating activity of a given F VIII preparation is independent of the total IgG it contains (M.M. Eibl et al, manuscript submitted). Control experiments using Sepharose not complexed with protein A also demonstrated that the Fc receptor modulatory activity was not removed by passage through Sepharose alone (data not shown).

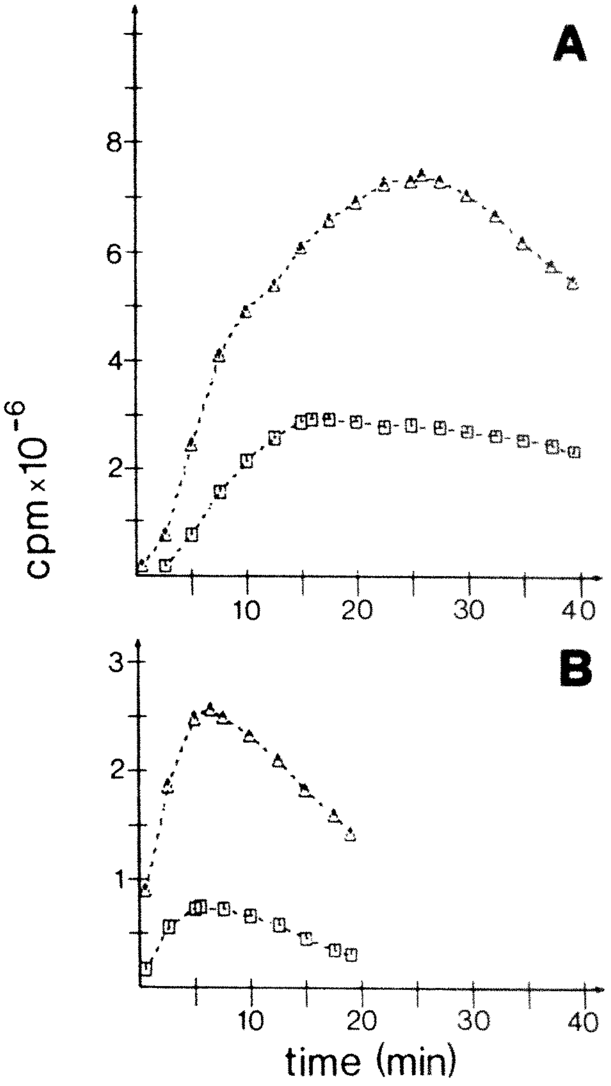

Fig 3. The capacity of human monocytes to secrete O_2 radicals is reduced by treatment with F VIII concentrate. Chemiluminescence induced by ingestion of zymosan (A) or IgG aggregates (B) was assessed 16 hours after pretreatment with PBS (△) or F VIII concentrate (□, 5 IU/mL). Chemiluminescence intensity measured in a bioluminescence counter is plotted as counts per minute (cpm) v time (minutes).

Effect of F VIII concentrates and F VIII concentrate fractions on monocyte effector functions. Since interactions with and ligation of Fc receptors are known to provide crucial triggering signals for intracellular microbicidal events,[25-27] it was of interest to determine whether the F

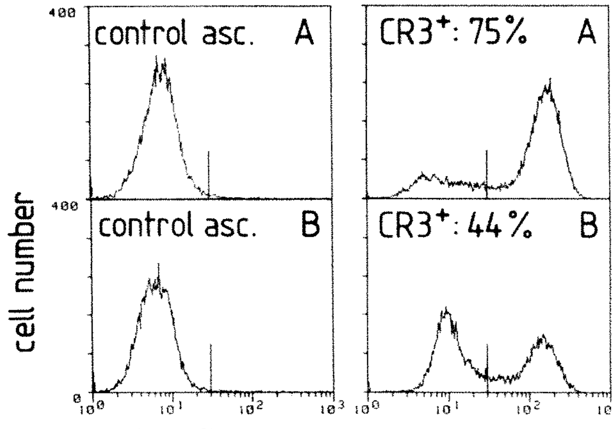

Fig 4. Interaction of F VIII concentrate with human monocytes leads to a decrease in the expression of CR3. iC3b receptor(CR3)-positive monocytes were assessed by indirect immunofluorescence and evaluated with a FACS 440 cell sorter. Sixteen hours after a one-hour pretreatment with buffer (A) or F VIII (2 IU/mL, B) monocytes were stained with the MoAb Mo1 (right panel) or with control ascites (left panel).

VIII-concentrate-mediated down modulation of Fc receptors would also modify monocyte effector functions. The data depicted in Fig 3 show that a one-hour pretreatment of Mo with 5 IU of F VIII concentrate 16 hours prior to the chemiluminescence assay led to a substantial reduction in the capacity of treated Mo to secrete O_2 radicals as compared to controls. The luminol-enhanced chemiluminescence was found to be reduced following stimulation of Mo by both opsonized zymosan and IgG aggregates.

The reduction of IgG aggregate-induced chemiluminescence can easily be explained by a decrease of Fc receptors in the Mo membrane. Chemiluminescence in response to zymosan is also decreased, but this substance stimulates the release of O_2 radicals by a pathway independent of Fc receptors, ie, following interaction with receptors for the complement cleavage product iC3b (CR3).[28] However, as can be seen in Fig 4, the expression of this receptor is also substantially diminished following preincubation of human monocytes with F VIII concentrate preparations. In that respect the Fc receptor-modulating component of F VIII concentrates behaves similarly to IgG polymers.[29]

In addition, pretreatment of Mo with F VIII concentrates also significantly down modulated these cells' capacity to kill microbes. *E coli* 089:H10, an *E coli* strain that requires opsonization by both antibodies and complement for proper elimination,[30] was used as a model system because this microorganism is easy to handle and is a potentially opportunistic pathogen. The data from Table 6 demonstrate that pretreatment of Mo with varying concentrations of F VIII concentrate preparations led to a dose-dependent reduction of the monocytes' bactericidal capacity (percent killing: controls [Mo pretreated with buffer] 64%, Mo pretreated with 2 IU/mL F VIII 50%, Mo pretreated with 5 IU/mL F VIII 34%, Mo pretreated with 10 IU/mL F VIII 22%). Similar results could be obtained if Mo were pretreated with fraction 1 (high Mr fraction [$Mr > 1,270,000$] eluting off the Biogel column after molecular sieving of F VIII concentrates). After pretreatment with fraction 1, the killing capacity of Mo was reduced to 36%, as compared to 64% obtained with control Mo (see Table 6, line 6).

DISCUSSION

Pretreatment of human monocytes with commercial F VIII concentrate preparations resulted in a down modulation of monocyte functions, as expressed by a reduction of Fc receptors and CR3 in the monocyte membrane, decreased release of oxygen metabolites following stimulation with opsonized zymosan and aggregated IgG, as well as impaired killing of bacteria.

Table 6. F VIII Pretreatment Reduces the Bactericidal Capacity of Human Monocytes

*Mo were pretreated with buffer or F VIII for one hour 16 hours prior to determination of the monocytes' bactericidal capacity.

†Number of bacteria surviving after a 90-minute incubation period, $\bar{x} \pm$ SEM of eight experiments.

‡% killing was calculated according to the following formula:

$$\%\ \text{killing} = \frac{\bar{x}\ \text{number}\ E\ coli\ \text{in control wells} - \bar{x}\ \text{number}\ E\ coli\ \text{in experimental wells}}{\bar{x}\ \text{number}\ E\ coli\ \text{in control wells}} \times 100$$

Significant (§$P < 0.05$ and ‖$P < 0.001$) increase as compared to the number of bacteria surviving in the presence of monocytes (pretreated with buffer), antibodies, and complement.

The first observation was that F VIII preparations inhibited rosette formation when added to Mo together with IgG-coated red cells. Since IgG-coated red cells are known to interact with the receptor for the Fc portion of IgG,[15] these findings indicated a competition of two similar ligands for the same binding site. Furthermore, polymeric (heat-aggregated) IgG and F VIII concentrates behaved very similarly in competitively inhibiting rosette formation as well as in down modulation of the Fc receptor. This down modulation was achieved by a short (one-hour) treatment of monocyte monolayers with therapeutic concentrations of F VIII 16 hours prior to the respective assays and was comparable whether heat-treated or non-heat-treated F VIII preparations were applied. Sequential treatment of Mo with polymeric IgG and F VIII concentrates did not increase the effect. Fractionation of F VIII concentrate preparations then clearly showed that the modulating activity was confined to a high Mr fraction ($Mr > 1{,}270{,}000$), which showed no F VIII activity and could be purified by affinity chromatography on immobilized protein A.

The molecular nature of this (these) contaminant(s) can be assumed to be (an) immunoglobulin aggregate(s) and/or (an) IgG-containing immune complex(es). In this context it is important to note that, as has already been shown in other studies,[22,31] monomeric IgG (which can also be detected in commercial F VIII concentrates[32]) is completely inactive in modulating monocyte functions (see Table 2, line 7).

The presence of immune complexes or IgG polymers in F VIII concentrate preparations might have important clinical implications. In a previous study we were able to demonstrate that interaction of monocytes and polymeric (heat-aggregated) IgG led to a down modulation of the monocytes' capacity to release O_2 metabolites (in response to triggering by both aggregated IgG and zymosan) and to kill microbes.[29] In the present paper we report a comparable effect induced by a high Mr component present in commercial F VIII concentrates. Immune complexes or IgG aggregates have also been shown to interfere with immune defense mechanisms in vivo. Recently Virgin and Unanue[33] provided direct evidence for a correlation between the presence of circulating immune complexes and decreased resistance to infection. Using *Listeria monocytogenes* infection of mice as a model system, these authors demonstrated that in animals previously immunized with an unrelated antigen, secondary antigenic challenge led to a dramatically decreased resistance to the intracellular pathogen. The finding that the decrease in resistance could only be observed if antigenic challenge and infection were given together or not further apart than one day points toward an influence of immune complexes on the early phase of infection. The presence of high levels of circulating immune complexes has also been shown to be one of the major factors for the predisposition to viral and bacterial infections in patients with rheumatoid arthritis.[34] These in vivo data as well as the results from our in vitro studies thus make it conceivable that—together with the already increased level of circulating immune complexes frequently observed in hemophiliacs[35,36]—the continuous inoculation of immune complexes or IgG aggregates caused by F VIII concentrate treatment contributes to the hemophiliacs' increased susceptibility to opportunistic infections.

Recent clinical evidence indeed supports the possibility of an underlying immune deficiency in hemophiliacs.[37] Children with bleeding disorders who had accidentally been exposed to tuberculosis in a hospital ward showed an unusual susceptibility to that disease. These children, who had been regularly treated with F VIII concentrates, were almost equally as susceptible to tuberculosis as children receiving immunosuppressive chemotherapy (38% of the hemophiliacs developed tuberculosis as compared to 48% of the children on immunosuppressive chemotherapy). Furthermore, a defect with respect to antigen presentation by monocytes has been described in both anti-HTLV III-positive and anti-HTLV III-negative hemophiliacs,[38] an effect that could also be achieved by pretreatment of monocytes from healthy subjects with therapeutic concentrations of F VIII concentrates (manuscript in preparation).

The in vitro data reported in the present publication strongly suggest that treatment with F VIII concentrates might contribute to an impairment of host-defense mechanisms in hemophiliacs. The bleeding disorder that comprises the major clinical problem in hemophiliacs is mainly treated by application of F VIII concentrates. Despite the availability of heat-treated F VIII concentrate preparations, which more or less rule out a de novo infection with HTLV III,[39,40] the possibility of inducing an immunosuppressed state by this treatment should still be kept in mind. Live HTLV III has been found in the circulation of hemophiliacs,[41] and since the virus is difficult to detect, it might be present in many more of the patients but inhibited from multiplying by a still functioning immune system. This delicate balance could be impaired by F VIII preparations contaminated with immune complexes and/or IgG aggregates. Therefore hemophiliacs now treated with heat-inactivated F VIII concentrate preparations should also be closely surveyed for immunologic functions and the possible outbreak of opportunistic infections. In addition, it appears desirable that F VIII concentrates free of immunosuppressive high mol wt contaminants should become available.

ACKNOWLEDGMENT

The authors wish to thank Henri Rengs for performing the bioluminescence assays and Christine Pruscha-Sitko for her help in determining the bactericidal capacity of monocytes.

The Regulatory Role of Interleukin 2–Responsive T Lymphocytes on Human Marrow Granulopoiesis

By Zeev Estrov, Chaim Roifman, Gordon Mills, Tom Grunberger, Erwin W. Gelfand, and Melvin H. Freedman

The effect of recombinant interleukin 2 (IL2) on marrow CFU-C colony formation was evaluated to define the role for T lymphocytes in human marrow granulopoiesis. The colony-stimulating factor (CSA) used in our experiments was found to contain IL2. IL2 depletion from CSA resulted in a reduction in CFU-C colony proliferation. Addition of exogenous IL2 caused an increase in CFU-C colony numbers in a dose-dependent manner. This increase could be prevented by anti-Tac, a monoclonal antibody (MoAb) to the IL2 receptor. Moreover, anti-Tac in the absence of exogeneous IL2 resulted in an overall decrease in colony numbers. Depletion of either adherent cells or T lymphocytes abolished the effect of IL2 and anti-Tac on colony growth. In the presence of IL2, re-addition of T lymphocytes to the T-depleted marrow or adherent cells to adherent cell-depleted marrow resulted in a significant increase in CFU-C colony numbers, whereas no significant effect was found when IL2-depleted CSA was used. Although T lymphocytes were not themselves essential for CFU-C colony growth, our studies indicate that IL2 and IL2-responsive T cells can regulate in vitro granulopoiesis.

© 1987 by Grune & Stratton, Inc.

CLONAL PROLIFERATION in vitro of committed granulocyte and monocyte-macrophage progenitor cells (CFU-C) is stimulated by glycoprotein molecules known collectively as colony stimulating activity (CSA).[1] Human monocytes and macrophages have been found to produce and release CSA[2-4] and when cultured with T cells in the presence of stimulatory antigen were found to produce much more CSA than either T lymphocytes or monocytes cultured alone.[5-7]

Although T cell lines[8-10] as well as mitogen-[2,11,12] or antigen-[12] stimulated T lymphocytes are able to synthesize CSA, T cell subpopulations have been reported to induce different effects on bone marrow (BM) CFU-C proliferation. Some investigators report stimulation of CFU-C growth, others have demonstrated inhibition, whereas still others have failed to identify any effect.[14-19]

Interleukin 2 (IL2), a secreted product of activated T cells[20] that is required for the proliferation of T cells, can enhance T lymphocyte production of a variety of colony-stimulating factors.[21] In the present study we used recombinant IL2 and a monoclonal antibody (MoAb) that blocks T cell-IL2 receptor sites[22] to demonstrate that IL2 responsive-T lymphocytes can interact with cells of the monocyte lineage to regulate in vitro granulopoiesis.

MATERIALS AND METHODS

Preparation of cells. Heparinized (10 U/mL) bone marrow (BM) was obtained after informed consent from hematologically normal adult volunteers who had been advised of the necessary procedures and attendant risks. These studies were approved by the Human Experimentation Committee at our institution. The BM cells were layered over Ficoll-Paque (Pharmacia Fine Chemicals, Piscataway, NJ) and centrifuged (200 × g, 4°C) for 20 minutes to remove neutrophils and red cells.

Adherent cell removal. The mononuclear cells were depleted of adherent cells by incubation on plastic Petri dishes with 10% fetal calf serum (FCS) in α culture medium for 90 minutes at 37°C. In this technique,[231] free-floating cells that did not adhere to the plastic dishes were removed by gentle pipetting and repeated vigorous washing of the plates with medium. This procedure was repeated until all free-floating nonadherent cells were removed.

The remaining adherent cells were then removed from the dishes by gentle scraping with a rubber policeman, washed twice, counted, and kept at 4°C. In the reconstitution experiments, 20% to 100% of the removed adherent cells were added back to 1×10^5 adherent cell-depleted BM cells.

Both cell fractions, adherent and nonadherent, were characterized on cytocentrifuge smears by counting more than 500 cells after Wright's stain, nonspecific (alpha naphthyl butyrate) esterase stain,[24] and immunocytochemistry[25] with anti-MY 4 MoAb (Coulter Immunology, Hialeah, FL) to identify monocyte-promonocyte cells. Using these techniques the nonadherent cell fraction that had been removed from the plastic incubation plates as described contained <3% monocytes. The adherent cell fraction consisted of >95% monocytes.

Double T cell depletion. Post-Ficoll BM mononuclear cells were incubated with neuraminidase-sensitized sheep erythrocytes (SRBC) at 4°C for two hours, followed by gradient centrifugation.[26] This procedure was repeated twice. Cells at the interface contained less than 0.5% T cells as assessed by AET-sensitized SRBC rosette formation[26] and using anti-Leu-4 and anti-Leu-5 monoclonal anti-T cell antibodies (Becton Dickinson, Mountain View, CA). T lymphocytes were obtained by recovery of rosetted cells from the pellet following lysis with Tris-buffered ammonium chloride. In the reconstitution experiments these T lymphocytes were washed, counted, and 25% to 100% of the removed T cells were added back to 1×10^5 T cell-depleted BM cells.

Lymphocyte removal using CAMPATH-1. BM cells obtained following Ficoll-Paque gradient centrifugation were then washed once in phosphate-buffered saline (PBS) and treated with a monoclonal rat antihuman lymphocyte antibody (CAMPATH-1) and complement, as previously described.[27,28] No residual T lymphocytes following this treatment were found by E rosette formation or by indirect immunofluorescence with anti-Leu-1, Leu-4, Leu-5 (Becton Dickinson, Mountain View, CA), or anti-T3 (Coulter Immunology).

Interleukin 2 (IL2). Recombinant IL2, derived from cDNA for the human IL2 gene expressed in *Escherichia coli*,[29] was provided by Biogen Research Corp, Cambridge, MA. The IL2 was reconstituted and, to confirm its activity, was tested in a sensitive, highly reproducible microassay based on tritiated thymidine uptake into the murine T lymphocyte line, 2.8.2, maintained in IL2-dependent long-term cultures.[30] This line does not respond to growth factors other than IL2. The material was also compared to IL2 obtained from the Gibbon cell line MLA 144, which showed similar effects. The stimulatory activity of the recombinant IL2 was blocked by anti-IL2 antibodies,[31] confirming the specificity of its effect. The concentration of biologically active IL2 was tested, defined and expressed in units using the murine IL2-dependent T cell microassay, as before.[30]

Anti-Tac antibody. Monoclonal anti-Tac antibody[22] with specificity for IL2 receptors was provided by W. Greene (National Institute of Health, Bethesda, MD). Its effect on an IL2-dependent T cell line was reversible after removal of the antibody, and could be overcome by high concentrations of IL2. Hybridoma supernatant tested as a control for anti-Tac was inactive in this system as well as in the CFU-C culture assay. Anti-Tac was added at the initiation of culture in dilutions of ascites fluid ranging from 1:333 to 1:1333. For control, anti-Leu-1 (Becton Dickinson, Sunnyvale, CA), a monoclonal pan-T antibody of identical subclass as anti-Tac (IgG_{2a}) was added to cultures in final concentrations of 0.025 to 1.0 µg/mL.

Preparation of CSA. Nucleated peripheral blood (PB) cells from a normal donor were immobilized in 10 mL of 0.5% agar (10^6 cells/mL) in 100-mm culture dishes. The cells were plated with and without 20 U/mL of IL2 and overlaid with 15 mL of 20% FCS in α-medium. The dishes were incubated for seven days at 37°C with 5% CO_2 in air in a humidified atmosphere. The cell-free supernatant was harvested, washed free of agar, tested on normal BM to determine its maximal activity, and stored in aliquots at −20°C.[32]

The biological activity of IL2 in CSA was tested in the murine IL2 dependent T cell microassay.[30] Standard CSA prepared from unstimulated PB cells (CSA-std) was found to contain 8 U/mL of IL2. CSA-std was depleted of IL2 activity using an anti-IL2 MoAb (provided by Dr K. A. Smith, Hanover, NH) bound to Affi-Gel (Bio-Rad Laboratories, Richmond, CA).[31] This IL2-depleted CSA (CSA-dep), when tested for IL2 activity, now contained 2 U/mL. In some of the experiments, CSA-dep was supplemented by adding 6 units to 33 units of IL2 (CSA-supp).

Highly purified human recombinant CSA (GM-CSF) that had no IL2 activity was provided by Steven C. Clark, Genetics Institute, Cambridge, MA. The preparation contained 220 µg/mL protein with a specific activity of 2×10^6 U/mg. A unit was defined as follows: a final concentration of 1 U/mL gave one half maximal colony formation.

CFU-C assay. The CFU-C assay was performed as described.[33] Briefly, nucleated BM cells (10^5) were cultured in 0.8% methylcellulose, 20% FCS, α-medium, and 20% CSA. The CSA concentration of 20% was used because it yielded maximum CFU-C growth-promoting activity. In one control study, recombinant GM-CSF 2 U/mL was substituted for 20% CSA. The culture mixture was placed in 35-mm Petri dishes in duplicate and maintained at 37°C, with 5% CO_2 in air, in a humidified atmosphere. Colonies were counted after 14 days using an inverted microscope. A CFU-C colony was defined as a cluster of 40 or more cells consisting of granulocytes, monocyte-macrophages, or both. Microscopically, granulocytic colonies could be easily distinguished from pure macrophage colonies because of the presence of smaller cells and tighter clustering. Individual colonies were plucked from the cultures with a micropipette and spread on glass slides, and the cellular composition was confirmed microscopically using Wright's stain and nonspecific (alpha naphthyl butyrate) esterase staining.[24]

Statistical analysis. The probability of significant differences between colony numbers was determined by Student's *t* test.

RESULTS

Comparative studies were performed to determine marrow CFU-C colony forming activity of the three CSA preparations. As a control, IL2 (35 U/mL) alone was added to cultures without CSA. The mean number of CFU-C colonies/culture produced in the presence of CSA-std, CSA-dep, and CSA-supp was 55, 32, and 140, respectively. IL2 alone yielded 36 colonies/culture. In control cultures prepared without CSA and IL2, the mean number of CFU-C colonies was 17. The differences in colony numbers between cultures with CSA-std and CSA-dep and between those with CSA-std and CSA-supp were significantly different ($P < 0.01$).

To further delineate the augmentative effect of IL2 on CFU-C growth, BM cells were cultured in four separate experiments with and without increasing concentrations of IL2 (Fig 1). The cultures were prepared with CSA-dep to confirm that the expected increments in colonies were IL2 dependent. The stimulatory effects of IL2 on CFU-C colony growth were evident in a dose-dependent manner ($P < 0.03$ comparing the highest concentration).

Similar dose-response studies were performed in four experiments with the anti-IL2 receptor antibody, anti-Tac (Fig 2). These cultures were prepared with CSA-std. The inhibitory properties of anti-Tac were observed to be dose-dependent ($P < 0.03$ comparing the highest concentration). In control cultures, anti-Leu-1, the monoclonal pan-T antibody of identical subclass as anti-Tac, had no effect on CFU-C colony growth.

To exclude the possibility of a nonspecific interaction between the crude preparations of CSA and IL2 or anti-Tac, IL2 and anti-Tac dose-response studies were repeated in cultures containing only recombinant GM-CSF 2 U/mL as the growth factor (Table 1). As shown, IL2 significantly increased ($P < 0.02$ with 20 U/mL) and anti-Tac decreased CFU-C numbers ($P < 0.04$ and <0.05 at dilutions of 1:300

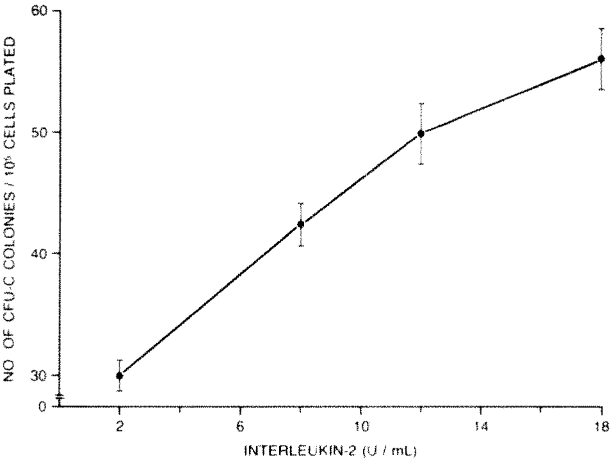

Fig 1. The effect of IL2 on CFU-C colony growth. Colony numbers from four experiments are expressed as mean ±SD. The CSA used in these studies (CSA-dep) contained 2 U/mL IL2. Increasing concentrations of IL2 were added to the CSA-dep.

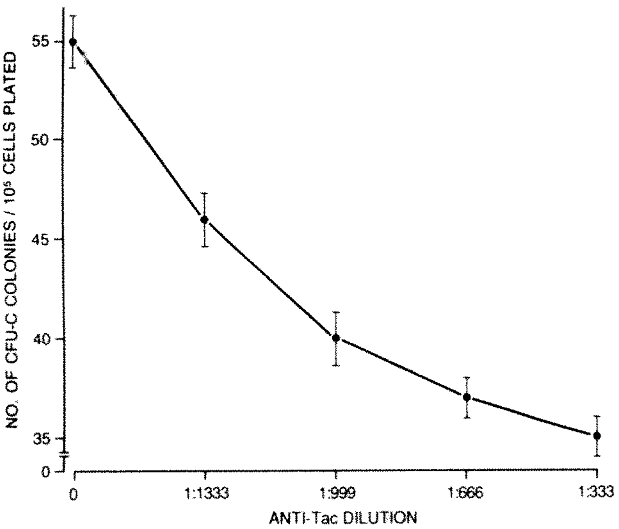

Fig 2. The effect of anti-Tac on CFU-C colony growth. Colony numbers from three experiments are expressed as mean ±SD. The CSA used in these studies (CSA-std) contained 8 U/mL IL2.

and 1:600, respectively) in a dose-dependent manner, identical to the previous studies.

To characterize which cell populations were involved in the modulatory effects exhibited by IL2 and the anti-Tac antibody, the effect of both agents was studied on BM samples that were depleted of T lymphocytes using CAMPATH-1. These studies were performed with CSA-std in the presence or absence of adherent cells (Fig 3). In the first column the stimulatory effect of IL2 on CFU-C colony numbers from post-Ficoll BM and the inhibitory effect of anti-Tac were both significant ($P < 0.01$ and $P < 0.025$, respectively). The removal from BM of either T lymphocytes (column 2) or the adherent cell fraction (column 3), or both (column 4), abolished the stimulatory property of IL2 and the inhibitory effect of anti-Tac.

To clarify the role of T cells in mediating the IL2 growth-promoting property on CFU-C colony formation, BM was depleted of T cells by rosetting and then reconstituted with varying T cell numbers (Fig 4). Using CSA-supp, no change in CFU-C colony numbers was observed until 50% of the removed T lymphocytes were added back to 1 × 10^5 T-depleted BM cells. Thereafter a T cell-dependent increase in CFU-C colonies was observed with a maximum increase over baseline of 100 colonies/culture when 100% of removed T cells were added back ($P < 0.001$). In control cultures with CSA-dep, no change in CFU-C colony numbers was seen on addition of T cells. Cultures of rosetted T lymphocytes plated alone with both preparations of CSA as control did not yield any CFU-C colonies.

The role of adherent cells on IL2-mediated CFU-C growth was examined in a similar manner. Adherent cells were

15 U/mL	69
20 U/mL	78
GM-CSF plus anti-Tac:	
1:1500	51
1:1000	51
1:600	38
1:300	35

All cultures contain GM-CSF 2 U/mL.

*Mean number of colonies from duplicate cultures is shown.

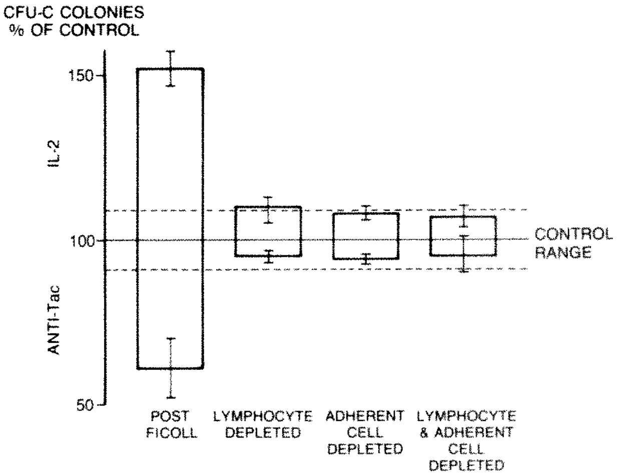

Fig 3. The effect of 15 U/mL IL2 and a dilution of 1:333 anti-Tac on four preparations of control BM. The data are from three separate experiments. CFU-C colonies are expressed as a percentage of the mean number of control colonies, which was defined as 100%. T lymphocytes were removed using CAMPATH-1. IL2 and anti-Tac were added to cultures using CSA-std containing IL2 8 U/mL.

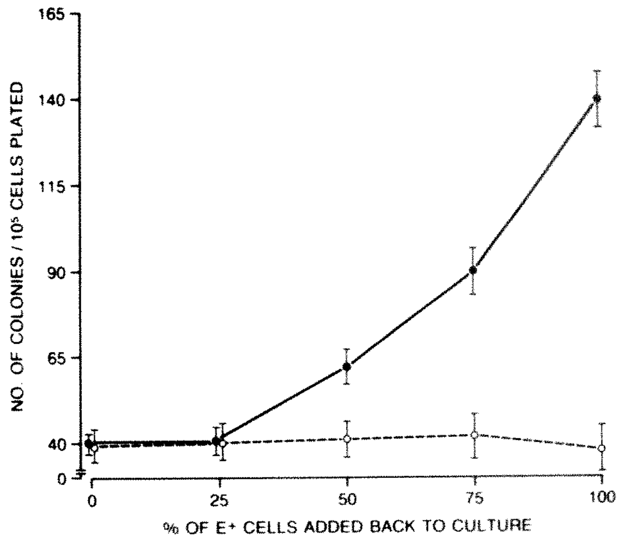

Fig 4. The effect of re-addition of rosetted T cell fraction to T-depleted BM in the presence of CSA-dep containing 2 U/mL IL2 (○—○) and CSA-supp containing 35 U/mL IL2 (●—●). Colony numbers are expressed as mean ±SD.

removed from the BM sample, and then added back to culture in varying numbers (Fig 5). Using CSA-supp, a significant increment in CFU-C colonies was found when 60% of the removed adherent cells were added to 1 × 10^5 adherent cell-depleted BM cells ($P < 0.01$) and plateaued ($P < 0.002$) when 80% to 100% of the removed adherent cells reconstituted the plated BM samples. No change in CFU-C colony numbers was seen in control cultures with CSA-dep on addition to adherent cells. Also, no CFU-C colonies developed when 2 × 10^5 adherent cells were cultured in the presence of CSA-std or CSA-supp.

To determine if IL2 could enhance CSA production from nucleated PB cells, the effect of CSA-std on CFU-C growth was compared to CSA prepared in the presence of IL2 20 U/mL (Fig 6). The BM was depleted of T cells and adherent cells prior to plating. At all four CSA concentrations tested, CFU-C colony numbers were higher in cultures containing the CSA prepared with IL2. At the highest CSA concentration tested, the difference in colony numbers between the two cultures was significant ($P < 0.01$).

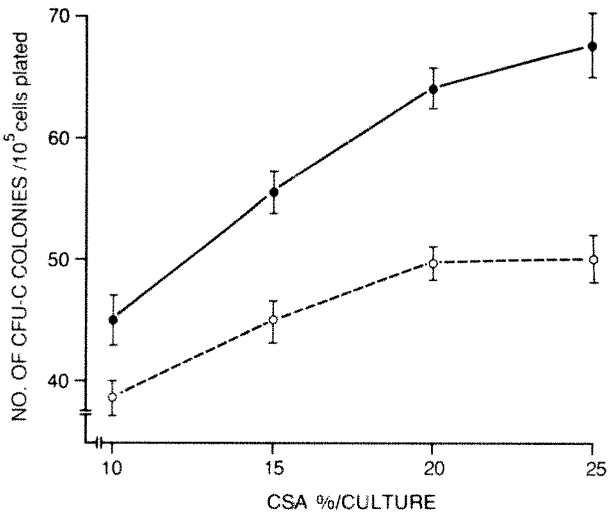

Fig 6. Comparison of four concentrations of CSA-std (O—O) and CSA prepared in the presence of IL2 20 U/mL (●—●) on CFU-C colony growth. The marrow sample was depleted of T cells and adherent cells prior to culture. Colony numbers are expressed as mean ±SD.

DISCUSSION

Previous studies have demonstrated the complicated cellular and humoral regulation of granulopoiesis.[2,8-19] A review of these publications, however, underscores many technologic problems, such as imperfect cell depletion methods, inadvertent enrichment of CFU-C when depleting other populations, and inability to quantitate or control interaction of the highly heterogenous subpopulations in normal marrow.

In the present study we examined the regulatory role on human marrow granulopoiesis by two BM subpopulations, IL2-responsive T lymphocytes and adherent cells. In an attempt to circumvent some of the technical problems that could flaw the study, we used recombinant IL2, a specific stimulator of activated T cells,[20,21] and the monoclonal anti-Tac antibody,[22] a blocker of IL2 receptor sites. Although other cell lineages are known to express receptor sites for IL2, only T lymphocytes are responsive to its action. Therefore IL2 and anti-Tac antibody in our studies were highly specific, and by stimulating or inhibiting an IL2-responsive T cell population, we were able to study the effect of these cells on CFU-C colony growth. The depletion of T lymphocytes by removal of E rosetting cells or by treatment with CAMPATH-1 abolished the effect of these cells on in vitro granulopoiesis, indicating that mature T lymphocytes can modulate CFU-C proliferation.

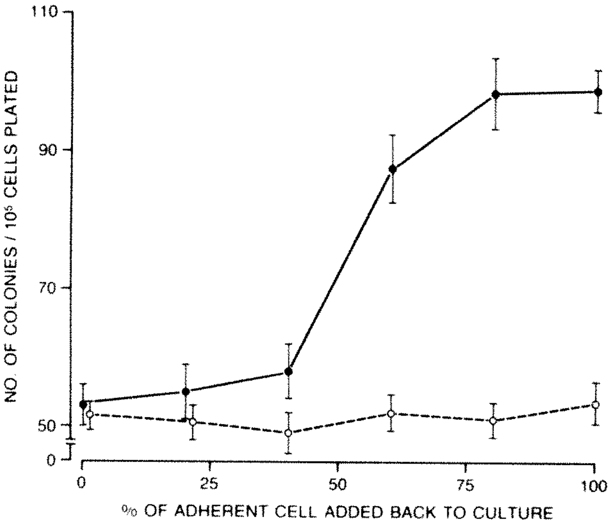

Fig 5. The effect of readdition of adherent cells to adherent cell-depleted BM in the presence of CSA-dep containing 2 U/mL IL2 (O—O), and CSA-supp containing 35 U/mL IL2 (●—●). Colony numbers are expressed as mean ±SD.

Our results showing IL2 enhancement and anti-Tac suppression of CFU-C colonies support previous reports suggesting that granulocyte-macrophage progenitor proliferation is controlled by T cells.[6,7,15,34,35] IL2-responsive T lymphocytes themselves have been reported to produce colony-stimulating factor,[21] but in our studies of fractionated BM, neither the IL2 nor the anti-Tac effects were observed when the adherent cells were removed from cultured BM cells. That is, IL2 and anti-Tac modulatory properties were expressed only in the presence of both BM adherent cells and T lymphocytes. Moreover, re-addition of T cells to the culture plates in the presence of 35 units IL2 and adherent cells increased CFU-C colony numbers in a dose-dependent manner. Similarly, re-addition of adherent cells to the cultures in the presence of IL2 and T cells increased CFU-C colony growth. These findings reflect the regulatory role of IL2 responsive T lymphocytes and the adherent cell fraction on CFU-C proliferation.

The requirement for BM adherent cells as well as T lymphocytes to mediate the modulatory properties of IL2 and anti-Tac on CFU-C growth contrasts with our findings for CFU-E and BFU-E proliferation.[36] Whereas IL2 resulted in an increase in marrow CFU-E and BFU-E colony numbers in a dose-dependent manner and anti-Tac had the opposite effect, identical to our CFU-C studies, depletion of marrow adherent cells did not alter the IL2 or anti-Tac effect on erythroid colony growth. Only the removal of marrow T lymphocytes blunted the effects of IL2 and anti-Tac on erythropoiesis. The data were consistent with the thesis that proliferating T cells released burst-promoting activity, (BPA) which, in turn, triggered erythroid progenitor proliferation.

In the CFU-C studies, the requirement for both cell populations suggests a different mechanism, probably one in which IL2-responsive T cells interact with adherent cells, which then elaborate CSA. This is strongly supported by our data on the CSA that was prepared from PB mononuclear cells in the presence of IL2 20 U/mL. That CSA preparation had significantly more activity on CFU-C growth than CSA-std when tested on T cell and adherent cell-depleted BM samples. Since IL2 did not stimulate CFU-C growth in the presence of either T cells or adherent cells but only in the presence of both, and since this CSA preparation was more active, we have to assume that a humoral factor that enhances CFU-C growth is released following the addition of IL2.

It had been previously reported that T lymphocytes and monocytes cultured together release more CSA than T cells or monocytes cultured alone.[5-7] Some investigators, however, failed to establish a clear role for T lymphocytes in either CSA production or regulation.[37] We have shown that CSA preparations contain IL2. Our standard CSA contained IL2 8 U/mL. Some investigators may not have appreciated this in the past. Clearly the IL2 content of CSA has important implications for marrow T cell replication and CFU-C growth. This was underscored by our study using highly purified recombinant GM-CSF that lacked IL2. The concentration of GM-CSF yielded maximum CFU-C colony growth, yet added IL2 augmented colony numbers even further. Using our CSA-std, the activity on CFU-C growth was reduced when IL2 was depleted and was enhanced by adding back IL2. These findings suggested an important regulatory role of IL2 in in vitro granulopoiesis.

Since in previous studies CSA was prepared in a similar manner, it is reasonable to assume that some of the conflicting results in the literature are due to dissimilar IL2 concentrations in different CSA batches. Motoyoshi et al[38] have suggested that some CSA species stimulate the BM adherent cells to produce endogenous CSA, which, in turn, causes CFU-C colony formation. This hypothesis may explain the ineffectiveness of IL2-responsive T cells on CFU-C growth in the absence of adherent cells.

T lymphocytes are not essential for CFU-C proliferation, since some CFU-C colony formation took place in the absence of T cells as well as in the presence of high concentrations of anti-Tac. Our findings, however, indicate that IL2, which is produced and secreted by T cells and has a central role in T cell function and immunity,[20,22,29,39] regulates in vitro granulopoiesis, probably by enhancing the interaction between T lymphocytes and adherent monocyte-macrophage cells.

Prevention of Pulmonary Injury in Isolated Perfused Rat Lungs by Activated Human Neutrophils Preincubated With Anti-Mo1 Monoclonal Antibody

By G. Ismail, M.L. Morganroth, R.F. Todd III, and L.A. Boxer

Neutrophil activation results in neutrophil adherence and may subsequently cause lung injury through the generation of oxidants, release of granule proteases, and generation of a variety of mediator substances. We hypothesized that inhibition of neutrophil adherence and subsequent lung sequestration would attenuate the lung injury caused by activated neutrophils. Using isolated perfused rat lungs, we determined if anti-Mo1 monoclonal antibody (binds to the α subunit of a neutrophil glycoprotein [gp 155,94] that facilitates adherence) would attenuate lung neutrophil sequestration and lung injury caused by human neutrophils stimulated by phorbol myristate acetate (PMA). PMA-stimulated neutrophils but not PMA or neutrophils alone caused lung injury as assessed by accumulation of ^{125}I-bovine serum albumin into lung parenchyma and alveolar lavage fluid. Incubation of neutrophils with anti-Mo1 antibody prior to stimulation with PMA attenuated lung injury and neutrophil sequestration. Furthermore, a histological survey revealed that anti-Mo1 antibody inhibited neutrophils present in the lung from spreading following exposure to PMA. Anti-Mo1 antibody did not inhibit PMA-stimulated neutrophil release of granule constituents or toxic O_2 metabolites as evidenced by lysozyme and lactoferrin release or the reduction of ferricytochrome *c* in the lung perfusate. The inhibition of lung injury caused by the anti-Mo1 antibody was not likely due to a nonspecific effect of the antibody, since another murine monoclonal antibody of the same class (anti-Mo5) did not inhibit lung neutrophil sequestration or lung injury. Thus, in this experimental model, interference with the close approximation of the neutrophil to its target site inhibited the ability of the activated human neutrophil to cause injury.

CONSIDERABLE EVIDENCE has accumulated over recent years suggesting that oxygen metabolites and proteases released by activated neutrophils may play an important role in the development of pulmonary inflammatory injury. Both oxidants and proteases have been detected in vivo in human disease and in models of pulmonary inflammation in experimental animals and isolated perfused lungs.[1-9] In experimental models of lung injury, acute lung damage can occur following a single dose of phorbol myristate acetate (PMA). This PMA-induced injury of rabbit lung vascular endothelial cells is dependent on the presence of neutrophils but the precise mechanism by which the neutrophil inflicts injury is not clearly understood.[10]

Following activation of neutrophils, not only do the cells release both proteases and oxidants, but they adhere more avidly to each other (neutrophil aggregation) and to artificial (plastic, glass) and physiological (endothelium, epithelium) surfaces.[11] Neutrophil adhesion which results in intimate contact between activated neutrophils and endothelial cells may be critical to the neutrophil's ability to inflict damage. These adhesion properties are necessary in order for activated cells to migrate on and through vascular endothelium in response to inflammatory stimuli. At the molecular level, progress has been made toward the identification of neutrophil surface glycoproteins that are involved in cell adhesion. Among these adhesion-promoting molecules is a heterodimeric glycoprotein, Mo1 (gp 155,95[12]) (equivalent to OKM-1[13] or Mac-1[14]) that also mediates the binding of C3bi-opsonized particles to the phagocyte membrane.[15] Monoclonal antibodies specific for the 155-kD alpha or 95-kD beta polypeptides of Mo1 have been shown to inhibit human neutrophil aggregation,[16,17] adhesion to plastic, glass, or endothelial cell surfaces,[18,19] and endothelial cell injury.[20]

With the availability of anti-Mo1 antibody the inhibition of neutrophil contact with its target can better be studied. We investigated in isolated salt-perfused rat lungs whether incubating human neutrophils with anti-Mo1 antibody prior to stimulation with PMA would inhibit lung neutrophil sequestration and subsequent lung injury. We also determined if anti-Mo1 antibody altered activated human neutrophil release of toxic oxygen metabolites or granule constituents. The isolated perfused rat lung was used in part since in this system we can concomitantly assess hemodynamic changes and the consequences of lung neutrophil activation (eg, sequestration, granule content release) over time. In this report, we demonstrate in isolated perfused rat lungs that PMA-activated human neutrophils induce acute lung injury which can be markedly attenuated by incubation of the neutrophils with anti-Mo1 antibody. The attenuation of the lung injury is not due to inhibition of neutrophil release of either superoxide or granule constituents. An identification of the mechanism by which neutrophils cause injury may lead to an understanding of the pathogenesis of some forms of the adult respiratory distress syndrome.

MATERIALS AND METHODS

Ex vivo lung preparation. An ex vivo model was used to assess lung injury and pulmonary vascular constriction following infusion of human neutrophils stimulated by PMA. Lungs were isolated from male Long-Evans rats (body weights 200 to 300g) which were anesthetized with pentobarbital (40 mg/kg intraperitoneally).

Lungs were isolated and perfused at constant flow at 0.03 mL/g rat body weight/minute as previously described.[21] Mean pulmonary artery inflow pressure ($\overline{PA}$) was measured with a Statham (Oxnard, CA) transducer and recorded on a Grass (Quincy, MA) recorder. Perfusion pressure was proportional to pulmonary vascular resistance, since the flow for a given lung was held constant. Left arterial pressure (pulmonary outflow) was set by adjusting the height of the outflow reservoir and was kept at 0 cm H_2O. The lungs were ventilated via a tracheal cannula with an air/gas mixture containing 21% O_2 and 5% CO_2 at a rate of 60 strokes/minute using a Harvard animal respirator. The lungs and perfusate reservoir were kept at a temperature of 37° to 40°C.

Lung perfusion. Lungs were perfused from the outset of the experiment from a reservoir containing physiologic salt solution (70 mL) osmotically stabilized with Ficoll (4 g/100 mL). The first 30 mL of lung effluent was discarded to eliminate circulating rat blood elements from the vascular space of the lungs. This resulted in no neutrophils being detected in a 1:4 dilution of perfusate in 3% acetic acid. The lungs were then perfused for 30 minutes to reach a stable perfusion pressure and temperature prior to adding ferricytochrome *c* (50 μmol/L) to the recirculating perfusate. Ferricytochrome *c* was added to the perfusate so that its reduction could be used as an index of superoxide generation. Ten minutes after the addition of ferricytochrome *c* to the perfusate, human neutrophils were added to the lung perfusate. In some experiments catalase (1,500 units) was added to the lung perfusate. In other experiments, human neutrophils were incubated with either anti-Mo1 or anti-Mo5 antibody.

Isolation of neutrophils. Human neutrophils (98% neutrophils with >1% platelets/1,000 cells) were isolated according to the method of Curnutte and Babior.[22] This procedure resulted in 95% viable neutrophils by the trypan blue exclusion test. The cells were washed and resuspended in a final concentration in the lung perfusate of 3 × 10^6 cells/mL.

Incubation of neutrophils with monoclonal antibodies. The generation of murine monoclonal antibodies anti-Mo1 (IgG2a)[12,23] and anti-Mo5 (IgG2a)[24] has been previously described. IgG was purified from ascites fluid by *Staphylococcus* protein A–sepharose chromatography.[24] Saturating concentrations of anti-Mo1 and anti-Mo5, as determined by using indirect immunofluorescence flow cytometry,[12] were 1μg/10^6 human neutrophils. In experiments where cells were pretreated with antibodies prior to administration into the lungs, 1.2 × 10^8 cells in 1 mL phosphate-buffered saline (PBS) were incubated for 15 minutes at 37°C with antibody concentrations far exceeding saturation (600μg/mL). Following incubation, neutrophils were delivered into the lung perfusate at a final concentration of 3 × 10^6 cells/mL without prior washing (monoclonal antibody present in the perfusate). To confirm antibody excess sufficient to saturate Mo1 sites expressed by neutrophils after PMA activation, perfusates from selected experiments were assayed for the presence of residual soluble anti-Mo1 antibody by indirect immunofluorescence against neutrophil indicator cells.

Administration of PMA. PMA (50 ng/mL perfusate) was added to the perfusion reservoir 10 minutes after the addition of neutrophils to the reservoir. In control experiments the same amount of PMA was added to a reservoir which lacked human neutrophils. In addition, in a separate series of studies, lungs were perfused from a reservoir containing human neutrophils but to which no PMA was added. Mean pulmonary artery pressure was measured before and for 60 minutes following the addition of PMA. Pulmonary venous effluent was sampled before and 10, 20, and 30 minutes following the addition of PMA for determination of neutrophil counts, ferricytochrome *c* reduction, and granule constituent release as described below. The dose of PMA used was chosen because amounts of PMA in excess of 50 ng/mL resulted in fulminant lung injury and precluded completion of the experimental protocol.

Measurement of lung injury. ^{125}I-bovine serum albumin (^{125}I-BSA) was prepared by the standard chloramine T method.[25] Unbound iodine was removed by gel filtration using a G-75 column. ^{125}I-BSA was added to the perfusion reservoir 30 minutes after the addition of PMA. This was done in part so that pulmonary venous effluence could be sampled and assays performed on venous effluent that did not contain ^{125}I-BSA. Thirty minutes after the addition of the ^{125}I-BSA to the perfusate, 1 mL of pulmonary venous effluent was obtained, weighed, and counted for two minutes in a gamma scintillation counter. This allowed the determination of the number of ^{125}I-BSA counts in 1.0 g of circulating perfusate.

The reservoir supplying perfusate to the lung was then changed to contain only physiologic salt solution osmotically stabilized with Ficoll (4 g/100 mL). After the lung was perfused with 15 mL of this perfusate, 1.0 mL of pulmonary venous effluent was obtained and assessed for radioactivity in a gamma scintillation counter. This was done to confirm that minimal ^{125}I-BSA counts (<1% of the counts present in 1.0 gram of the circulating perfusate) remained within the intravascular space of the lung. The lungs and attached structures were then weighed prior to performing whole lung lavage, which was done by instilling 3.0 mL of normal saline into the tracheal cannula. This was instilled and withdrawn three times and 1 to 1.5 mL of total fluid was recovered. One mL of this lavage fluid was then counted for two minutes in a gamma scintillation counter to assess the amount of ^{125}I-BSA that accumulated in alveolar lavage fluid. The structures attached to the lung tissue were then dissected away from the lung and weighed. This weight was subtracted from the previously determined weight of the lung with attached structures to determine lung wet weight. The lung tissue was then counted for two minutes in a gamma scintillation counter to assess the amount of ^{125}I-BSA that had accumulated in lung parenchyma. ^{125}I-BSA counts present in alveolar lavage fluid, lung tissue, and pulmonary venous effluent were normalized by dividing the number of counts measured by the number of ^{125}I-BSA counts present in 1.0 g of circulating perfusate. The ratio of lung wet weight to the rat body weight was calculated as an index of lung water.

To assess neutrophil–pulmonary endothelial interactions in situ, a light and transmission electron microscopic survey of lung sections was performed comparing lungs perfused with neutrophils alone, neutrophils plus PMA, and neutrophils incubated with anti-Mo1 antibody plus PMA. Thirty minutes following the addition of the neutrophils to the perfusion reservoir the lung was fixed with 4% glutaraldehyde via tracheal instillation (at 15 cm H_2O). Sections (1 μ) were examined following staining of plastic-embedded tissue with toluidine blue.

Analysis of lung perfusate. The number of circulating neutrophils in the perfusate were counted on a hemocytometer. Perfusate samples that contained an undetectable number of cells at a 1:4 dilution in 3% acetic acid were considered devoid of circulating neutrophils. Ferricytochrome *c* reduction was used as an index of superoxide generation and was determined by optical density measurement of the perfusate at 551 nm. In separate experiments, it was demonstrated that the reduction of ferricytochrome *c* was abolished by the addition of superoxide dismutase (50 μmol/L) to the perfusate. Lysozyme activity (units/min/mL) and lactoferrin concentration (μg/mL) were measured as described previously.[26,27]

Assay for hydrogen peroxide generation. Hydrogen peroxide generation by resting and stimulated neutrophils was determined by the method of Root and Metcalf.[28] Neutrophils (2.5 × 10^6/mL) in Krebs-ringer-phosphate, pH 7.4, were incubated with 5 ng/mL PMA or 10^{-7} mol/L f-Met-Leu-Phe (FMLP) for 15 minutes. In some instances, 50 μmol/L ferricytochrome *c* was added to the buffer in order to evaluate the effect of this scavenger of superoxide on hydrogen peroxide formation.

Statistics. Values were expressed as mean ± SEM. Groups were

compared using one-way analysis of variance and the Neuman-Keuls multiple comparison test.

RESULTS

Effect of anti-Mo1 antibody on lung neutrophil sequestration and lung injury. Addition of human neutrophils to rat lung perfusate containing physiologic salt solution in the absence of PMA caused $\overline{PA}$ pressure to increase 3 ± 0.4 mm Hg (n = 9, Fig 1). More than 95% of the neutrophils entering the lung were sequestered, since they were not recovered in the pulmonary venous effluent (Table 1, experiment A). Despite lung neutrophil sequestration, in the absence of PMA there was no increase in rat lung wet weight to body weight ratio or increase in accumulation of ^{125}I-BSA into lung parenchyma or alveolar lavage fluid (Fig 2, column two). Similarly, as seen in Fig 2, column one, PMA alone in the absence of neutrophils failed to cause increased rat lung weight to body weight ratio or increase in accumulation of ^{125}I-BSA into lung parenchyma or alveolar lavage fluid.

Neutrophils could not longer be detected in the lung effluent following the addition of PMA to lung perfusate containing neutrophils (Table 1, experiment A). Correspondingly, in these lungs the administration of PMA resulted in lung injury as assessed by increased rat lung weight to body weight ratio and increased accumulation of ^{125}I-BSA into lung parenchyma and alveolar lavage fluid (Fig 2, column three). This increased albumin accumulation in lung parenchyma and alveolar lavage fluid was not likely due to hydrostatic changes since the $\overline{PA}$ pressure measured during the period of albumin accumulation (12 ± 2 mm Hg) in these lungs (human neutrophils [PMN] and PMA) was not different (p = NS) from the $\overline{PA}$ pressure measured (10 ± 2 mm Hg) when only PMA was added to the lung perfusate. Generation of H_2O_2 was necessary for the lung injury to occur since addition of catalase (n = 5) to the lung perfusate prior to the addition of PMA inhibited the increased accumulation of ^{125}I-BSA in lung parenchyma (.36 ± .06, $P < .05$).

Incubation of neutrophils with anti-Mo1 antibody inhibited lung neutrophil sequestration both prior to and following the addition of PMA to the lung perfusate (Table 1, experiment B). Incubation of neutrophils with anti-Mo1 antibody had no effect on the $\overline{PA}$ pressure increase following addition of these neutrophils to the lung perfusate (3 ± .4 mm Hg, n = 6, P = NS). However, addition of PMA to lung perfusates containing neutrophils incubated with anti-Mo1 antibody resulted in less lung injury since the increase in lung wet weight to body weight ratio and accumulation of ^{125}I-BSA into lung parenchyma and alveolar lavage fluid were inhibited (Fig 2, column four). This inhibition of the lung parenchyma and alveolar lavage albumin accumulation was not likely due to hydrostatic changes, since the $\overline{PA}$ measured during the period of albumin accumulation (10 ± .6 mm Hg) in these lungs (PMN incubated with Mo1 antibody and PMA) was not different (P = NS) from that in lungs in which nontreated neutrophils were stimulated by PMA (12 ± 2 mm Hg). Lung albumin accumulation was also compared in a subset of lungs from each of these two groups. Lungs were paired such that the $\overline{PA}$ pressures during the period of albumin accumulation were identical (<.5 mm Hg difference). Comparing these subgroups (paired *t* test, n = 3) addition of PMA to lung perfusates containing neutrophils incubated with anti-Mo1 antibody, as opposed to nonincubated neutrophils, still resulted in less accumulation of ^{125}I-BSA into lung parenchyma (.43 ± .09 *v* 1.1 ± .1, $P < .05$) and alveolar lavage fluid (.03 ± .01 *v* .36 ± .3, $P < .05$). Treatment of neutrophils with anti-Mo1 antibody not only reduced the total number of cells sequestered in the lung, but anti-Mo1–treated neutrophils failed to spread on pulmonary endothelium after exposure to PMA as assessed microscopically (Fig 3, column C). In addition, the vascular endothelium appeared intact following exposure to PMA-stimulated neutrophils incubated with anti-Mo1 antibody. However, the anti-Mo1 antibody did not impair the development of vacuolization, a finding consistent with degranulation. In contrast, as seen in Fig 3, column B, PMA-activated neutrophils not exposed to anti-Mo1 antibody underwent spreading on endothelium, caused marked endothelial cell damage, and demonstrated vacuolization consistent with

Table 1. Circulating Neutrophils in Perfusate Following Infusion of Untreated or Antibody-Treated Human Neutrophils

	Before PMA Injection			After PMA Injection	
Experimental Conditions*	Neutrophils (× 10^5 Cells/mL)	Percentage Recovery†	P Value‡	Neutrophils (× 10^5 Cells/mL)	Percentage Recovery†
A. PMN alone	1.58 ± 0.63	4.9 ± 1.95		ND§	—
B. PMN-AbMo1	7.03 ± 1.07	23.3 ± 3.54	$P < 0.05$	0.36 ± 0.12	1.2 ± 0.39
C. PMN-AbMo5	2.50 ± 0.82	8.2 ± 2.68	P = NS	ND	—

*Neutrophils were added to the reservoir in a concentration of 3 × 10^6 cells/mL.

†Percentage recovery was calculated by dividing the number of neutrophils measured in 1 mL of pulmonary venous effluent by the number of neutrophils in the lung perfusate entering the lung.

‡P values represent comparisons between PMN alone and each of the other two conditions.

§ND indicates no neutrophils detected in a 1:4 dilution of perfusate in 3% acetic acid.

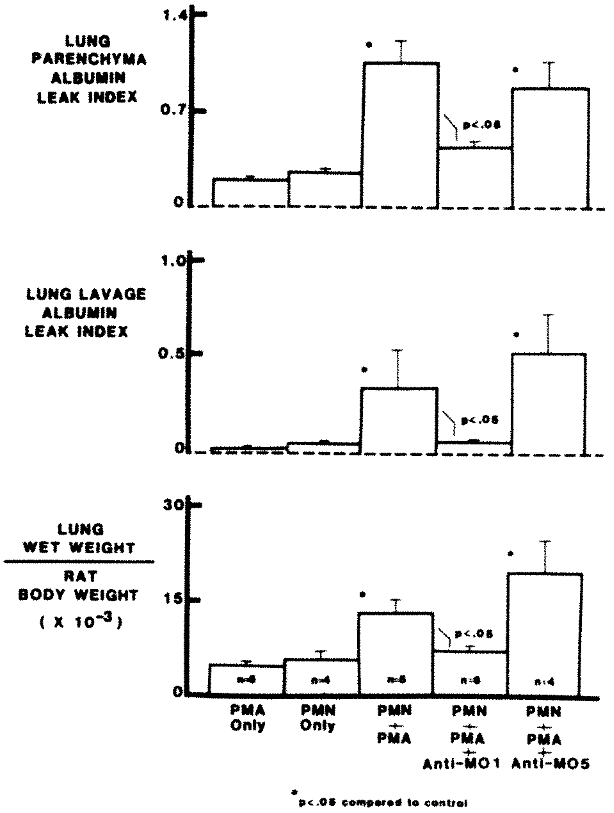

Fig 2. Effects on lung injury of PMA by itself (PMA only), unstimulated neutrophils (PMN only), and PMA-stimulated neutrophils with or without prior incubation with anti-Mo1 or anti-Mo5 monoclonal antibodies. Lung parenchyma and alveolar lavage albumin leak indices were calculated by dividing the ^{125}I-BSA counts in lung tissue or alveolar lavage fluid by the ^{125}I-BSA counts in 1.0 g of perfusate. n equals number of lungs studied. Control refers to lungs to which only PMA was added (no neutrophils).

degranulation. Neutrophils not stimulated by PMA, like neutrophils treated with anti-Mo1 antibody, remained round and did not undergo spreading on or injure the vascular endothelium (Fig 3, column A). As a specificity control for the effect of anti-Mo1 antibody, in parallel experiments neutrophils were incubated with an isotype-identical murine monoclonal antibody (anti-Mo5).* Anti-Mo5 antibody failed to prevent neutrophil sequestration in the lung (Table 1, experiment C), or the PA pressure increase following the addition of the neutrophils to the perfusate (3 ± 0.6 mm Hg, n = 4, P = NS), or lung injury induced by the subsequent addition of PMA (Fig 2, column 5).

Effect of anti-Mo1 antibody on granule enzyme release. PMA stimulation of human neutrophils in the lung perfusate resulted in the secretion of the specific granule components lysozyme and lactoferrin into the lung perfusate (Fig 4). The addition of PMA in the absence of neutrophils resulted in no detectable increase in granule components. Incubation of human neutrophils with anti-Mo1 antibody had no significant effect on release of granule constituents into the lung perfusate following the addition of PMA. On the other hand, mere exposure of nonstimulated human neutrophils to rat lung endothelium led to the release of a small but significant (p < .001) amount of lactoferrin.

Effect of anti-Mo1 antibody on ferricytochrome c *reduction.* Stimulation of neutrophils with PMA caused a time-dependent reduction of ferricytochrome c in the lung perfusate (Fig 5). The average rate of ferricytochrome c reduction by untreated, anti-Mo1–, and anti-Mo5–treated neutrophils occurred at 30 nmol/min/10^7 cells during the first ten minutes following stimulation with PMA. There was no significant reduction of ferricytochrome c in perfusates containing either PMA or neutrophils alone. PMA-stimulated human neutrophils preincubated with either anti-Mo1 or anti-Mo5 antibody produced rates (P = NS) of ferricytochrome c reduction comparable to those observed with nontreated neutrophils.

Effect of extracellular ferricytochrome c *on PMA-stimulated H_2O_2 generation.* As shown in Table 2, ferricytochrome c totally inhibited H_2O_2 release from FMLP-stimulated cells. In contrast, the amount of H_2O_2 release detected from cells stimulated by PMA was only partially attenuated by the presence of ferricytochrome c.

DISCUSSION

Following stimulation, activated neutrophils are able to damage neighboring target tissues such as endothelial cells. This model has been broadly adopted to explain inflammatory vascular damage such as lung injury in the adult respiratory distress syndrome.[10] Because neutrophils are capable of releasing a broad spectrum of effector substances, neutrophil contact with vascular endothelium may be relevant to the pathogenesis of vascular injury and subsequent pulmonary edema. Previous studies have directed considerable attention toward the mechanisms by which neutrophils adhere to endothelium in vivo and in vitro. It has been observed that monoclonal antibodies directed against the Mo1 surface glycoprotein can inhibit neutrophil aggregation and their adhesion to substrates.[15] Employing cells from a patient with a congenital deficiency of adhesive glycoproteins, Harlan et al found that activated neutrophils from the patient failed to induce disruption of an endothelial monolayer or increase ^{125}I-albumin passage through the monolayers.[29] Activated control neutrophils caused a nonlytic disruption of the endothelial monolayers which was mediated by an oxygen radical–independent mechanism.[29] In contrast, Shasby et al demonstrated a neutrophil-mediated increased albumin passage across endothelial monolayers by an oxygen-dependent mechanism.[30] Since the cultured monolayers may not mimic the response of endothelium in vivo, we chose to study the effect of neutrophil activation on changes in permeability using an intact vasculature. We found that treatment of human neutrophils with anti-Mo1 monoclonal

---

*Anti-Mo5 recognizes a neutrophil plasma membrane protein (Mo5) of unknown function.[24] Anti-Mo5 monoclonal antibody represents a good control for the effects of anti-Mo1, since by immunofluorescence analysis[24] the density of Mo5 is equivalent to that of Mo1 on the surface of unstimulated human neutrophils. Moreover, exposure of neutrophils to degranulating stimuli results in an increase in the surface expression of both Mo1 and Mo5[24] (Mo5 being somewhat less than Mo1).

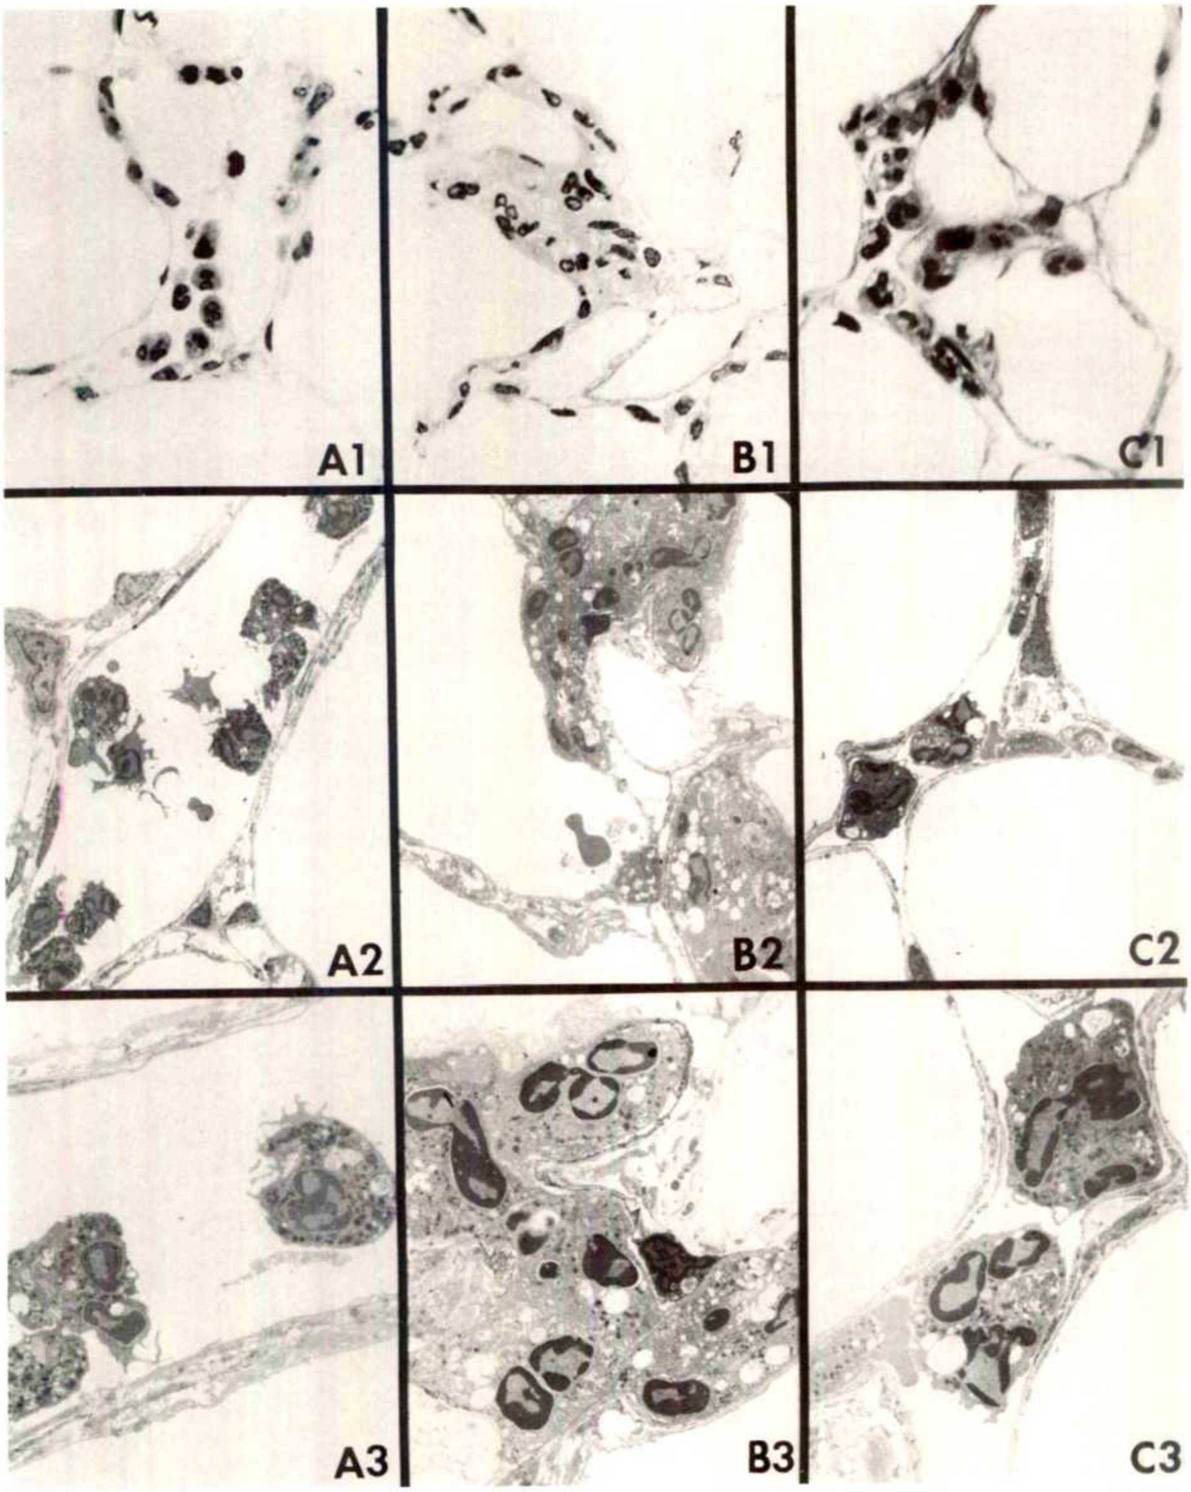

Fig 3. Photomicrographs of rat lungs exposed to human neutrophils. Line 1 original magnification 400×, current magnification; line 2 original magnification 2,600×, current magnification; line 3 original magnification 5600×, current magnification. Column A shows nonstimulated human neutrophils. Column B shows PMA-stimulated human neutrophils. Column C shows PMA-stimulated human neutrophils incubated with anti-Mo1 antibody. As seen in Column B, stimulation of PMNs by PMA resulted in the close approximation of the neutrophil to the endothelium and vacuolization consistent with degranulation. Gross endothelial cell injury is evident. Anti-Mo1-treated PMA-stimulated PMNs (Column C) or unstimulated PMNs (Column A) remained round and endothelial damage was not evident. Anti-Mo1 antibody did not prevent the development of PMN vacuolization. A contaminating red blood cell is seen in B2.

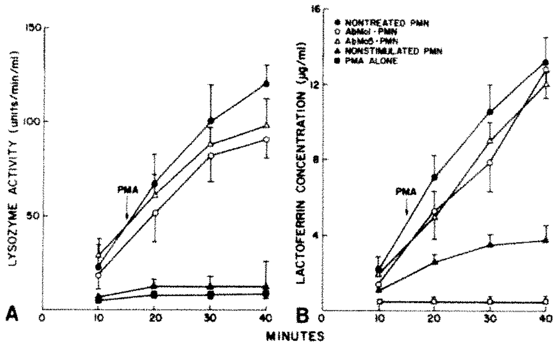

Fig 4. Release into lung perfusate of specific granule constituents (A) lysozyme and (B) lactoferrin over time. The time of addition of PMA is also shown (downward arrow). Nontreated PMNs (n = 5) refers to PMA-stimulated PMNs not incubated with a monoclonal antibody. AbMo1-PMN (n = 4) and AbMo5 (n = 4) refer to PMA-activated PMNs incubated with anti-Mo1 or anti-Mo5 antibody, respectively. Nonstimulated PMN (n = 4) refers to lung perfusates to which only PMNs were added. PMA alone refers to lung perfusates to which only PMA was added (no neutrophils added). There was a significant increase ($P < .05$) in lactoferrin over time for all groups except PMA alone. There was a smaller increase ($P < .05$) for nonstimulated PMNs compared to stimulated PMNs whether incubated or not incubated with monoclonal antibody. There was a significant increase ($P < .05$) in lysozyme release only for the three groups of neutrophils stimulated by PMA. The open squares in (B) refer to PMA alone.

antibody attenuated lung injury following exposure of neutrophils to PMA. The attenuation of the lung injury likely resulted from the inability of the neutrophils to undergo spreading and firmly attach to vascular endothelium. Simon et al[31,32] have demonstrated in epithelial cell cultures that incubation of PMA-stimulated neutrophils with Mo1 antibody inhibits cell injury. Although the Mo1 antibody did not prevent attachment of the neutrophils to the epithelial cells, it prevented neutrophil spreading and their close approximation to the target cells.

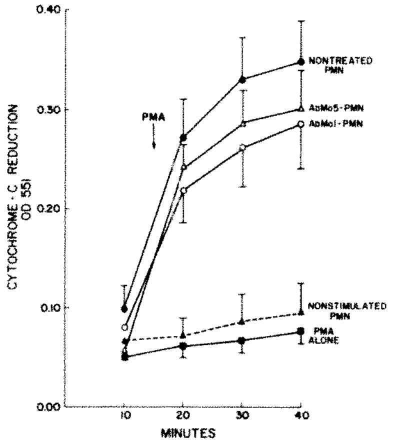

Fig 5. Reduction of ferricytochrome *c* only occurred in PMA-activated neutrophils whether or not they were incubated with a monoclonal antibody. There was no difference (P = NS) in the reduction of ferricytochrome *c* accompanying PMA-activated nontreated PMNs or PMNs incubated with anti-Mo1 antibody or anti-Mo5 antibody.

Table 2. Effect of Extracellular Ferricytochrome C on PMA- and FMLP-Stimulated H_2O_2 Generation

Experimental Conditions	H_2O_2 Generation (nmol H_2O_2/15 Min/5 × 10^6 Cells)	Percent Inhibition
PMN, FMLP	14.2 ± 1.2	
PMN, ferricytochrome *c*, FMLP	0	100%
PMN, PMA	123.6 ± 6.4	
PMN, ferricytochrome *c*, PMA	84.2 ± 5.4	32%

Experiments were performed on isolated human neutrophils in a test tube system containing 5 × 10^6 cells/mL and 50 µmol/L ferricytochrome *c*.

We demonstrated that treatment with anti-Mo1 monoclonal antibody did not prevent the PMA neutrophil–induced lung injury by inhibiting the production of potentially noxious substances such as oxidants and granule proteases. This is consistent with in vitro studies that have shown that anti-Mo1 antibody does not inhibit degranulation or superoxide production.[23] Finally, inhibition of lung injury did not arise from a nonspecific effect of a murine IgG2a antibody, since anti-Mo5, an IgG2a antibody that recognizes another neutrophil membrane constituent,[24] failed to attenuate lung injury.

One of the apparent advantages of our isolated perfused rat lung–human neutrophil system is the ability to quantify neutrophil activation in situ by monitoring both the generation of oxidants and the release of specific granule constituents into the perfusate. We found that the presence of ferricytochrome *c* in our lung perfusate did not quantitatively alter acute pulmonary injury of PMA-activated neutrophils as compared to those experiments carried out in the absence of ferricytochrome *c* (data not shown). A possible explanation for the lack of inhibition of injury by ferricytochrome *c* may be explained by the ability of PMA to initiate vesicles within intact neutrophils that are sequestered from the direct inhibitory effect of the superoxide scavenger. Other investigators have shown that during contact of human neutrophils with opsonized particles, the presence of ferricytochrome *c* failed to completely abolish H_2O_2 release from the cells. In contrast, there was no detectable H_2O_2 release from neutrophils pretreated with cytochalasin B to prevent phagosome formation in the presence of ferricytochrome *c*. These data suggest that the formation of "privileged sites" within the phagosome that are inaccessible to ferricytochrome *c* can lead to the generation of diffusable H_2O_2. In our model, ferricytochrome *c* which was used as an extracellular indicator of superoxide production likely did not scavenge superoxide formed within the neutrophil. Cytochemical studies previously have demonstrated that PMA induces formation of cytoplasmic vesicles and channels in neutrophils which exhibit H_2O_2 staining.[33] It is likely that PMA stimulation of the human neutrophils in our lung model induced similar vesicles hidden from the scavenging effect of ferricytochrome *c*. Indeed, we showed that the rate of H_2O_2 formation by PMA-stimulated human neutrophils in vitro was not completely abolished in the presence of extracellular ferricytochrome *c*, indicating that a substantial amount of H_2O_2 produced during PMA stimulation escaped the scavenging effects of ferricytochrome *c*. In contrast, neutrophils activated by FMLP, which leads to total release of superoxide to the extracellular environment, were inhibited from generating H_2O_2 by the presence of ferricytochrome *c* in the supernatant.

We found that pretreatment of neutrophils with anti-Mo1 antibody failed to completely inhibit sequestration of unstimulated neutrophils or cells exposed to PMA. The detection of residual soluble anti-Mo1 monoclonal antibody in lung perfusate even after PMA administration (which has previously been shown to induce an increase in surface Mo1 expression by neutrophils[34]) indicates that the concentration of anti-Mo1 antibody used in these experiments was far in excess of that required to saturate all neutrophil Mo1 antigenic sites. Another possible explanation of the failure to completely prevent cell adherence may relate to the existence of other adherence-promoting leukocyte surface antigens besides that recognized by our anti-Mo1 reagent. In support of this possibility are studies of Harlan, Beatty, Wallis, and their colleagues[18,19,35] in which a monoclonal antibody (60.3[36]) directed against the 95-kD β chain that is common to Mo1 and two other surface heterodimeric glycoproteins (LFA-1 and pl50,95) resulted in a significant inhibition of the adhesion of neutrophils[18,19] and monocytes[35] to endothelial surfaces. Whether the structurally related glycoproteins LFA-1 and p150,95 are also involved in neutrophil adhesion[37] is a subject for further study.

In our studies, we observed that the exposure of neutrophils to rat endothelium resulted in the release of a small but significant amount of the specific granule constituent lactoferrin. These observations are similar to reports by other investigators who have found that attachment of neutrophils to surfaces leads to exocytosis of specific granule constituents.[38] Despite the release of granule constituents, this was insufficient to lead to detectable lung injury in our system. Similarly, PMA by itself or by stimulating cells present in the lung did not lead to the intravascular generation of superoxide or lung injury. This is in contrast to the report by Dyer[39] demonstrating a neutrophil independent effect of PMA on lung injury in sheep.

In conclusion, PMA-activated human neutrophils in isolated perfused rat lungs induced acute edematous injury which could be markedly attenuated by incubation of the neutrophils with anti-Mo1 antibody. The extent of lung injury paralleled that observed in isolated rat lungs utilizing a homologous system employing rat neutrophils and rat plasma activated by the complement activator cobra venom factor.[25] In this homologous system lung injury was also neutrophil-dependent, since the activation of complement by cobra venom factor in plasma-perfused lungs in the absence of neutrophils did not result in lung injury. Anti-Mo1 antibody did not inhibit the release of either superoxide or granule constituents but led to an increase in the number of circulating cells in the perfusate, suggesting that the attenuation of lung injury by the monoclonal antibody resulted from interference of neutrophil adhesion to the endothelial cell surface by the specific monoclonal antibody. These studies indicate the necessity of intimate neutrophil–endothelial cell contact for the initiation of target cell injury.

Increased Susceptibility of Peripheral Mononuclear Cells of Leukemic Patients to HTLV-I Infection In Vitro

G. Graziani, D. Pasqualetti, M. Lopez, C. D'Onofrio, A.M. Testi, F. Mandelli, R.C. Gallo, and E. Bonmassar

Peripheral mononuclear cells (MNC) collected from 12 healthy donors and 44 leukemic patients at various stages of the disease were tested for natural killer (NK) activity and for their susceptibility to HTLV-I infection in vitro, measured in terms of percentage of p19 positive cells. MNC from leukemic donors at any stage of leukemia (ie, onset or relapse, ON/REL; complete remission or off-therapy, CR/OT donors) were highly susceptible to HTLV-I infection. This was true for acute leukemias of lymphoblastic (ALL) or nonlymphoblastic (ANLL) type. MNC of ON/REL patients were more susceptible to HTLV-I than those of CR/OT donors. In addition, leukemic blasts were more rapidly infected (ie, within five to seven days) than the HTLV-I–susceptible normal cord-blood lymphocytes. However, the presence of circulating blasts was not essential to virus susceptibility, since CR/OT MNC, presumably free of leukemic blasts, were still more susceptible to HTLV-I than normal cells. Basal NK function of MNC from leukemic patients was significantly lower than that detectable in healthy controls. However, no correlation was found between susceptibility to HTLV-I infection and NK activity.

HUMAN RETROVIRUSES of different HTLV groups have been isolated from patients affected by certain T cell malignancies in various geographic areas, and have been implicated in the development of the disease.[1-9] The HTLV-I subgroup was found to be able to infect T lymphocytes in mixed cultures in vitro between virus-producer donor cells and susceptible target lymphocytes, especially when umbilical cord blood[10,11] or bone marrow[12] lymphocytes were used as target cells. Adult T lymphocytes appear to be more resistant to infection than relatively immature target cells, as evidenced by studies on the expression of the HTLV-I structural protein p19 on target cell membrane, and DNA blot hybridization to detect the HTLV-I provirus integrated in the host cell genome.[13]

In order to study the host cell range and the regulation of HTLV-I infection, we have investigated whether the relatively immature lymphocytes present in the peripheral mononuclear cells (MNC) of leukemic patients would be highly susceptible to in vitro infection with the virus. The results of the present investigation confirmed this hypothesis and provided additional evidence that peripheral blood lymphocytes of patients in complete remission (ie, without evidence of circulating leukemic blasts) are still more susceptible to HTLV-I infection than normal T lymphocytes of adult donors.

MATERIALS AND METHODS

Cell lines. The human erythroleukemia K562[14] cell line was used as a target for the NK activity of effector lymphocytes in a four-hour ^{51}Cr release assay. MT-2, a HTLV-I producer cell line, was obtained by in vitro coculture of normal human cord-blood lymphocytes and adult T cell leukemia cells (ATL) positive for HTLV-I.[15] MOLT-4 is a T cell line obtained from peripheral blood cells of a young patient with acute lymphoblastic leukemia (ALL).[16] These cell lines were maintained as stationary suspension cultures in culture medium RPMI 1640 supplemented with 20% fetal calf serum (FCS) and 2 mmol/L glutamine (GIBCO, Grand Island, NY) plus 50 μg/ml of gentamycin (hereafter referred to as complete medium [CM]).

Leukemic patients. Peripheral mononuclear cells (MNC) were collected from 44 leukemic patients, including 27 adults (15 male and 12 female patients) and 17 children (10 male and seven female donors). The age range for adults was between 16 and 62 years, and that for children was between 3 and 14 years.

The diagnosis was ALL in 37 patients, being one of B, nine of T, and 27 of non-T, non-B phenotype. The remaining seven patients had acute nonlymphoblastic leukemia (ANLL). The number of patients at different stages of the disease is illustrated in Table 1. MNC were collected from off-therapy patients at least one year after the end of maintenance therapy, from patients in complete remission during maintenance therapy, and from patients at the onset or relapse of the disease, before starting induction therapy. In addition, in three cases the samples were collected from the same donor in two different stages, ie, in remission and in relapse, 2 to 3 months later. Chemotherapy regimens used for remission induction and for the maintenance of remission include the use of vincristine, daunorubicin, L-asparaginase, adriamycin, prednisone for induction therapy, and methotrexate, vincristine, and cytarabine for maintenance therapy as previously described.[17]

Cocultures. Recipient MNC were separated from peripheral blood by centrifugation on Ficoll-Hypaque gradient. Virus producer MT-2 cells (2×10^6) were lethally irradiated (12,000 R) and cocultured with recipient MNC (10^7) in 25-cm^2 flasks in CM (5 mL final volume) containing 10% of T cell growth factor (TCGF or IL-2).[10,18,19] The cultures were fed with fresh CM plus TCGF (Cellular Products, Buffalo, NY) twice a week or more frequently, depending on the growth rate. Control irradiated MT-2 cells were also cultured separately and no viable cells could be detected after three days of culture.

Irradiation of tumor cells in vitro. MT-2 tumor cells were irradiated in vitro using a ^{137}Cs irradiator (Gamma Cells 1000, model "A", AECL, Canada) delivering gamma rays at the rate of 1,000 rads/min, suspended in CM in 15-mL tubes at a concentration of 10^6 cells/mL. The cells were then washed twice and resuspended in the same medium.

Table 1. Susceptibility to HTLV-I Infection of Target Peripheral Blood MNC Cocultivated In Vitro With HTLV-I Producer Cells

Donors of Target Cells*	Adult	Child	ALL†	ANLL‡	Total	p19-Positive	Samples	P§			
						Number	(%)	P1	P2	P3	P4
Healthy controls	7	5	—	—	12	0	0	<0.01	<0.01	—	—
Off Therapy (OT)	1	5	6	0	6	3	50.0	—	—	—	NS‖
Complete Remission (CR)	9	8	17	0	17	12	70.6	—	—	—	—
Onset + Relapse (On + Rel)	17	4	13	8	21	21	100.0	—	—	<0.05	—
Total leukemic	27	17	36	8	44	36	80.0	—	—	—	—

*Target cells were cocultivated with irradiated (12,000 R) HTLV-I producer MT-2 lymphoblasts (see Materials and Methods). Leukemic donors include all donors affected by leukemia, listed under OT(off-therapy 1 to 10 years), CR (complete remission, under maintenance therapy), and On + Rel (Onset + Relapse). Target cells of On + Rel donors contained various percentages of blasts.

†ALL, acute lymphoblastic leukemia.

‡ANLL, acute nonlymphocytic leukemia.

§*P*, probability calculated according to chi-square analysis, comparing the percentage of p19-positive samples as follows: *P*1, healthy controls *v* leukemic; *P*2, healthy controls *v* OT + CR; *P*3, OT + CR *v* On + Rel; *P*4, OT *v* CR.

‖NS, not significant.

Assay for HTLV-I infection. Infection with HTLV-I, inducing p19 protein expression in host cells, was determined by calculation of the percentages of p19 positive leukocytes. Fixed cells were analyzed by indirect immunofluorescence for the presence of HTLV-I p19 internal virus component using a murine monoclonal antibody specific for the purified p19 protein, and rabbit antimouse F(ab)2 IgG conjugated with fluorescein isothiocyanate (FITC, Cappel, Cochranville, PA) as previously described.[20]

Surface phenotype analysis of cells by monoclonal antibodies. Identification of cells positive for antigens reactive with different monoclonal antibodies and conventional surface markers (E rosette and sIg) were carried out as previously described in detail.[21,22] Murine monoclonal antisera specific for subsets of human T lymphocytes,[23,24] eg, T cells (OKT3), E rosette receptors (OKT11), the helper/inducer T cells (OKT4), cytotoxic/suppressor T cells (OKT8), immature hematopoietic stem cells (OKT10), tranferrin receptor (OKT9), histocompatibility locus D antigens (HLA-DR)[25] and antigen expressed on monocytes (OKM 1)[26] were used to label live cells. Positive cells were identified using FITC-labeled goat antimurine IgG F(ab)2-specific serum (Kallestad, Delta Biologicals, Rome). OKT reagents were purchased from Ortho Pharmaceutical Corp. (Raritan, NJ), and the other reagents from Becton Dickinson FACS Systems (Sunnyvale, CA).

Terminal deoxynucleotidyl transferase. A cytocentrifuge preparation of peripheral blood cells was fixed in methanol for 30 minutes, washed in PBS for 10 minutes, and analyzed for terminal deoxynucleotidyl transferase (TdT) utilizing rabbig IgG antihuman TdT and, subsequently, FITC-labeled goat antirabbit IgG (Bethesda Research Laboratories, Bethesda, MD).

Blast purification on Percoll gradients. Blast purification on Percoll gradients was performed as described by Hakos.[27] Briefly, MNC obtained after separation on Ficoll-Hypaque gradients were further layered on two Percoll gradients. Percoll was diluted with RPMI 1640 plus 50 μg/mL of gentamycin to concentrations of 40% (1.06 g/mL) and 36% (1.05 g/mL); then 5 mL of 40% Percoll was placed at the bottom of a 15-mL tube (Falcon, Oxnard, CA) followed by 5 mL of 36% Percoll over which MNC were stratified. Tubes were centrifuged at 550 g for 30 minutes, and blast cells were concentrated at the 36% interface, while small mature lymphocytes were placed at the bottom of the tube.

DNA preparation. High molecular weight DNA was extracted by proteinase K digestion followed by organic solvent extraction, according to standard procedure.[28]

Dot blot analysis. 3 μg of DNA from each sample were denatured just before spotting by incubation in 0.2 mol/L NaOH for 10 minutes at 65°C. The samples were then neutralized by adding 1 vol of 2 mol/L NH_4 acetate. The DNA samples were spotted on a nitrocellulose filter (Schleicher and Schüll, Dassel, FRG) previously saturated in 1 mol/L NH acetate. The filter was dried and then baked for two hours at 80°C. Prehybridization was performed for three hours at 65°C on a shaking platform in 4× SET buffer (NaCl 3 mol/L, TRIS 0.06 mol/L, EDTA 40 mmol/L), and 10× Denhart (polyvinylpirrolidone, bovine serum albumin, and Ficoll), 0.1% sodium dodecyl sulfate (SDS) (Sigma, St Louis), and 100 μg/mL salmon sperm. The filters were then hybridized in the same solution with a ^{32}P nick-translated HTLV-I probe (3×10^6 cpm/mL, specific activity 2×10^8 cpm/μg). The HTLV-I probe is a Sst I subclone from a MT-2 genomic clone containing the complete virus.[29] The filters were washed in a solution of 10× Denhart, 4× SET, and 0.1% SDS for 30 minutes and successively in 2× SET and 0.1% SDS for 30 minutes, both on a shaking platform at 65°C. The filters were exposed to X ray film with an intensifying screen ("X-Omatic," Kodak, Rochester, NY) for 66 hours.

Cytotoxicity assay. The NK activity was determined using a ^{51}Cr release assay, as previously described.[30] Briefly, graded concentrations of effector cells (E) were suspended in CM containing 25 mmol/L HEPES buffer, mixed with 2×10^3 ^{51}Cr-labeled target cells (T) in round-bottom 96-well microtiter plates (Greiner C.A. and Söhne, Nurtingen, FRG) (final volume 0.2 mL) and incubated for four hours in a 5% CO_2 incubator. At the end of the incubation period the plates were centrifuged (800 g for 10 minutes) and the radioactivity of 0.1 mL of the supernatant was measured in a γ-scintillation counter (Packard Instrument, Downers Grove, IL). The baseline ^{51}Cr release was that released spontaneously from target cells and in no case did it exceed 10% of the total radioactivity incorporated by target cells. Experimental results were expressed as the percentage of specific lysis over the spontaneous release and were calculated as follows:

$$\% \text{ specific lysis} = \frac{\text{cpm(t)} - \text{cpm(s)}}{\text{cpm(T)}} \times 100$$

where cpm(t) is the mean cpm released in the presence of effector cells, cpm(s) is the mean cpm released spontaneously by target cells, and cpm(T) is the total amount of ^{51}Cr incorporated into target cells.

Calculation of lytic units. Dose–response curves were obtained by plotting the percentage of specific ^{51}Cr-release and the effector–target (E/T) ratios. The best-fit curve for this function was found to be logarithmic in accordance with previous reports.[31] A lytic unit (LU10) was defined as the number of effector cells extrapolated from the dose–response curve which was required to achieve n% specific target cell lysis. The amount of LU10/10^6 effector cells was calculated by dividing 10^6 by the number of lymphocytes corresponding to 1 LU10. The cytolytic activity was considered low when it was less than 1 LU10/10^6 cells. The mean ± standard deviation (SD) of LU10/10^6 cells of normal lymphocytes preparation was found to be 26.4 ± 12.7. Therefore, low-activity samples were considered those below the mean minus 2 SD (ie, 1 LU10/10^6 MNC).

RESULTS

Peripheral MNC obtained from healthy donors and leukemic patients at various stages of the disease were cocultured with irradiated infecting MT-2 cells and tested for p19 expression at weekly intervals for 5 weeks. The results illustrated in Table 1 show that MNC of leukemic patients were particularly susceptible to HTLV-I infection, as evidenced by the significant percentage of samples which became p19-positive within 1 to 5 weeks of coculture (Table 1, *P*1). The increased susceptibility to HTLV-I infection with respect to that of normal MNC was particularly evident in MNC collected from donors at the onset or relapse (On + Rel) stage of the disease, which is associated with the presence of blast cells in peripheral blood and bone marrow. This was true for ALL or ANLL. In the latter instance the number of T lymphocytes, targets of the virus infection,[9-11,15] was very limited, being the leukemia cell population largely represented by myeloblasts.

The data in Table 1 show also that putatively normal lymphocytes obtained from patients off-therapy (OT) and those in complete remission (CR) were significantly more susceptible to HTLV-I infection than normal adult MNC (Table 1, *P*2), whereas no difference in virus susceptibility was found between MNC of OT and CR donors (Table 1, *P*4). However, the statistical analysis of the percentage of p19-positive samples indicates that MNC of On + Rel donors were more susceptible to HTLV-I infection that those collected from OT + CR patients (Table 1, *P*3).

These findings were further supported by the kinetic analysis of virus infection illustrated in Fig 1, showing that MNC containing blast cells (of On + Rel donors) were more rapidly converted to p19-positive cells following exposure to MT-2 HTLV-I than MNC collected from OT + CR patients. Moreover, leukemic samples, especially those collected from On + Rel donors, were more readily infected than those of normal umbilical cord blood MNC (Fig 1).

The close association between p19 positivity and virus infection was confirmed by the finding that cells carrying the p19 antigen were also positive for HTLV-I provirus. This was evidenced by DNA dot blot analysis, using the DNA extracted from infected MNC of ALL and ANLL donors and a nick-translated ^{32}P-labeled probe containing almost the entire HTLV-I genome (Fig 2). Moreover, control cocultures were carried out mixing leukemic cells of an ANLL donor or of in vitro growing MOLT-4 cell line with irradiated Epstein-Barr virus (EBV)-infected human B lymphoblastoid cells (X_3O_3 line). In this case the cocultures remained consistently negative for the p19 antigen during up to 2 weeks of observation. On the other hand, the same target cells cocultivated with the irradiated MT-2 line showed high percentages of p19-positive cells as early as at four days of coculture (data not shown).

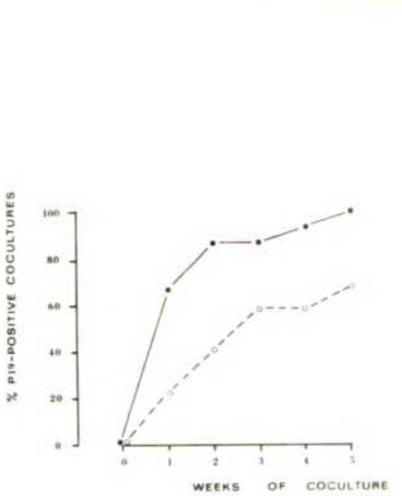

Fig 1. Time course of appearance of p19 positivity after HTLV-I infection of MNC obtained from On + Rel (●—●, 15 cases), or OT + CR (○—○, 15 cases) donors, cocultured with irradiated MT-2 cells. Chi-square analysis of the percentages of p19-positive cocultures (ie, showing more than 10% p19-positive cells) showed a significant difference between the two groups ($P < 0.05$) at 1, 2, 4, and 5 weeks postinfection. Eight different samples of cord-blood lymphocytes cocultured with HTLV-I donor cells at the same conditions showed no positivity after 2 weeks of coculture. Eighty percent of the samples were positive (ie, showing more than 10% p19-positive cells) at 3 weeks and 100% at 4 weeks of coculture.

Cell phenotype of T lymphocytes infected in vitro with HTLV-I was found to be predominantly of helper/inducer class, ie, positive for the surface antigen recognized by OKT4 monoclonal antibody and positive for HLA-DR determinants.[32] Similarly, the majority of the phenotype markers associated with infected MNC of the leukemic patients described in the present study were found to be reactive with OKT4 and anti-HLA-DR antibodies. This is shown in a typical example of surface phenotype patterns of infected MNC of ALL donors, as illustrated in Table 2. In this case blast cells containing 10% only of OKT4 positive lymphocytes yielded an infected line expressing predominantly the OKT4 phenotype. In addition "normal" lymphocytes of an OT donor infected by HTLV-I virus generated a cell line represented largely by OKT4 blast cells (Table 2). However, the data obtained in the present study pointed out also that pure ANLL blasts, deprived of T lymphocytes, were rapidly infected by the virus. Blast cells from peripheral blood obtained from ANLL donors were purified on Percoll gradients as described in Materials and Methods. The cells were cocultured with irradiated MT-2 donor cells and tested for

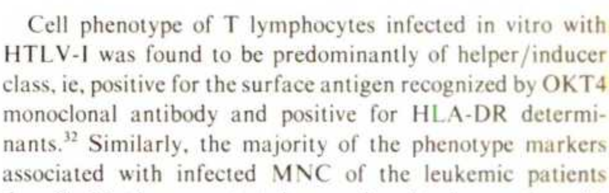

Fig 2. A representative experiment of dot blot analysis on genomic cellular DNA is shown. HTLV-I provirus is integrated in the DNA obtained, respectively, from two p19-positive cocultures (A and B) which survived more than 5 weeks. Cocultures were performed using recipient MNC bearing the phenotype of ANLL (onset) M5 variant (A), and of ALL (onset) T cell variant (B), respectively. Positive control (C) is DNA extracted from HTLV-I donor MT-2 cells. Negative control (D) is DNA extracted from the p19-negative erythroleukemia K562 cell line.

Table 2. Cell Surface Markers of MNC of an ALL Patient Before or After Infection With HTLV-I

Leukemic Cells		Blasts	Percent of Positive Cells							
Code	Type	%	p19	OKT3	OKT4	OKT8	OKT9	OKT11	Tdt	HLA-Dr
MT-2	H/CB	100	100	—	100	—	ND	45	ND	100
CC	B-ALL (ON)	90	0	30	10	4	50	5	+	0
CC/MT-2	H/B-ALL (ON)	90	90	70	90	5	82	70	—	100
CF	cALL (OT)	0	0	70	49	28	0.1	71	—	12
CF/MT2	H/cALL (OT)	90	85	39	93	—	ND	30	ND	100

Abbreviations: H/CB, HTLV-I infected cord blood cell line; B-ALL (ON), acute lymphoblastic leukemia (B cell variant); ON, onset; H/B-ALL (ON), HTLV-I–infected ALL, tested on day +54 of coculture with irradiated MT-2 cells; cALL (OT), acute lymphoblastic leukemia (common type); OT, off therapy; H/cALL (OT), HTLV-I–infected ALL tested on day +48 of coculture with irradiated MT-2 cells; ND, not done.

p19 positivity and phenotypic markers on days 5, 11 and 22 of coculture. The results (Table 3) show that blasts were HTLV-I–positive as early as five days after the coculture and retained their original surface markers. Actually no cell of the T lymphocyte lineage, reactive with "pan T," OKT3, or OKT11 antibodies could have been detected in this HTLV-I–positive line.

The studies concerning the basal NK function of MNC of various origins, measured before coculturing with the virus producer MT-2 cells, are illustrated in Tables 4 and 5. The results expressed in terms of geometric mean of LU10/10^6 MNC or as percentage of samples showing low NK activity (LNK, ie, less than 1 LU10/10^6 MNC, see Materials and Methods) reported in Table 2 show that: (*a*) NK activity was significantly lower in lymphocytes of leukemic patients than that detectable in healthy controls. Moreover, the percentage of LNK samples was higher in leukemic donors than that detectable in healthy controls; (*b*) the NK activity and percentage of LNK samples found among OT + CR patients did not reach a statistically significant difference from those detectable among donors bearing active disease (On + Rel patients); and (*c*) the percentage of LNK samples was significantly higher in MNC preparations.

DISCUSSION

Considerable experimental evidence is now available showing that HTLV-I can be transmitted in vitro to a variety of target cells, using cell-to-cell transfer in tissue culture.[10-13] There are a number of studies demonstrating that cocultivation of HTLV-I–producing cells with recipient cells is far more efficient for transmitting the retrovirus than is extracellular HTLV-I.[10] The data presently available suggest also that preferential target cells of the virus would be human T lymphocytes carrying the OKT4 marker. This appears to be especially true in the case of spontaneous HTLV-I–positive cells of patients with adult T cell leukemia–lymphoma[33] or of cord-blood lymphocytes infected by in vitro cocultivation with virus-donor cell lines.[32] However, when bone-marrow recipient cells were used for in vitro HTLV-I transmission, infected T cells were alternatively of OKT4+, or OKT8+ or OKT4−/OKT8− phenotypes.[12] The host range for HTLV-I infection appears to be even larger in selected experimental conditions, since B-cells[34] and cells of nonlymphoid origin,[35] including endothelial cells,[36] have been successfully infected with the virus. In any case, the pattern of HTLV-I transmission in vitro shows preferential susceptibility of lymphoid cells at relatively immature stages (eg, cord blood or bone marrow cells), whereas adult MNC appear to be more resistant to virus infection.[13,37]

Therefore, it was anticipated that mononuclear cells collected from patients with lymphoproliferative disorders would have been particularly susceptible to the infection with the retrovirus, especially when immature hemopoietic cells are present in the peripheral blood.

Preliminary data have shown that cultured human leukemic lines are highly susceptible to HTLV-I infection (P. Markham, personal communication, February 1985). The results of the present study confirm that circulating MNC, including blast cells of leukemic patients, are easily and rapidly infected with the virus. However, the increased susceptibility to HTLV-I infection of cells derived from leukemic donors was found not only in MNC of On/Rel patients but also in those collected from CR/OT donors. Actually, in the case of MNC of CR/OT origin, appreciable

Table 3. Time Course of Appearance of p19-Positive Cells and Expression of Cell Surface Markers of Purified ANLL Blasts* Cocultured With Irradiated MT-2 Cells

	Percentage of Positive Cells

amounts of target immature lymphocytes do not appear to be present. Moreover, no increase of the proliferative response of CR/OT MNC in MNC/MT-2 coculture was found with respect to that detectable in normal MNC/MT-2 coculture (data not shown).

In any case, the present studies demonstrated that MNC containing blast cells (of On/Rel donors) are more rapidly converted to p19-positive cells following exposure to MT-2 HTLV-I than lymphocytes from CR/OT donors, as shown in Fig 1. This is consistent with previous studies showing that proviral integration is favored by target cell proliferation,[12] as expected to occur in leukemic blasts. That OKT4 cells were the primary target of virus infection seems to be confirmed by the findings described in Table 2, showing that infected HTLV-I lines were predominantly of OKT4 phenotype.

This occurred also in the case of B-cell leukemia containing a limited number of OKT4-positive lymphocytes. In this case, however, one cannot rule out the possibility that target leukemic B cell blasts could have been converted by HTLV-I infection to cells carrying T cell–like markers, including determinants cross-reactive with the OKT4 antigen.

Table 5. Relationship Between Time of HTLV-I Infection Expressed in Terms of Week(s) of the Appearance of p19-Positive Cells and Basal NK Function

Week of p19 Positivity*	No. of Observations	LU10/10^6 MNC GM (SE)†
1	14	0.140 (0.033-0.59)
2	6	0.048 (0.004-0.58)
3	4	7.900 (2.7-23.2)
5	3	0.036 (0.001-1.27)

*Time in week(s) of appearance of more than 10% p19-positive cells, after day 0 of coculture between recipient and virus-producing MT-2 lymphoma cells.

†In parentheses: mean − standard error (SE) and mean + SE. The Pearson r coefficient for the relationship between the week of p19 positivity and the levels of NK function expressed in terms of LU10/10^6 MNC is −0.123, showing that there is no relationship between the two parameters.

In the case of MNC collected from On/Rel of ANLL leukemic patients, the "preferential" immature T targets of HTLV-I did not appear to be present in the cocultures (Table 3) and yet rapid and total conversion to p19-positive cells occurred (Tables 1 and 3). This could be explained considering that early and successful in vitro transmission of HTLV-I could occur in target cells other than immature T lymphocytes and in particular blast cells of myeloid origin.

The possible role of NK function in virus transmission in vitro has been considered in the present study, as illustrated in Tables 2 and 3.

A number of reports in the literature suggest that natural immunity, at least in part represented by the NK system, would be involved in immune surveillance against the outgrowth of transformed cells and cancer progression.[38,39] The observation that NK activity of HTLV-I–resistant MNC of normal donors is greater than that of HTLV-I–susceptible MNC of leukemic subjects (Table 4) seems to support this hypothesis. However, in the case of HTLV-I–susceptible MNC obtained from leukemic patients at any stage of the disease, one would expect that MNC samples with low NK activity were more susceptible to HTLV-I infection, or more rapidly infected by the virus than those with high NK activity. Since this was not the case (Tables 4 and 5), it can be suggested that virus infection is not profoundly affected by the NK system, at least within MNC of leukemic donors, although the number of observations is too low to detect a limited influence of natural immunity on virus transmission. This possibility is also supported by the observation that the majority of the p19-positive transformed lines are scarcely susceptible to NK-mediated cytolysis (data not shown). As already mentioned, the majority of MNC preparations obtained from healthy donors were associated with high NK activity. Therefore it is reasonable to assume that additional properties, distinct from NK function, would be responsible for the relatively high HTLV-I resistance found in normal adult lymphocytes.

In conclusion, the results obtained in the present study show that: (*a*) leukemic MNC are more susceptible to HTLV-I infection than normal lymphocytes; (*b*) morphologically normal lymphocytes of leukemic patients, off-therapy or in complete remission, are more susceptible to HTLV-I than T cells of healthy donors; and (*c*) no convincing evidence was found that the level of basal NK activity markedly affects the susceptibility of leukemic MNC to viral infection.

The reason for this is not presently known. It might well be a consequence of altered interaction among cellular genes that follows the drug therapy and/or the leukemic transformation.

ACKNOWLEDGMENT

Membrane Receptors for Interleukin 2 on Hematopoietic Precursors in Chronic Myeloid Leukemia

By Giuseppe Visani, Ruud Delwel, Ivo Touw, Frederik Bot, and Bob Löwenberg

In this report we present data on the expression of IL2 receptors on chronic phase CML cells. Using an anti IL2 receptor monoclonal antibody (McAb aIL2r) in indirect immunofluorescence we found significant proportions (42.2% ± 19.7 SD) of the CML cells (previously depleted of E rosetting T cells) to be IL2 receptor positive following incubation in suspension for 18 hours at 37°C. Noninduced cells did not express IL2 receptors. After induction the aIL2r positive and negative cell subpopulations were sorted and analyzed separately for morphology, lineage specific cell surface markers, and clonogenic cell numbers. The IL2 receptor positive CML subpopulations mainly contained blast cells and monocytes and revealed reactivity with myeloid McAbs but not with T cell, B cell, platelet, or erythroid markers. Clonogenic cells (CFU-GEMM, BFUe, and CFU-GM) were selectively recovered from aIL2r positive CML cells and thus were IL2 receptor positive. The addition of recombinant IL2 (rIL2) to CFU-GM and BFUe cultures, in concentrations from 50 to 500 U/mL, did not influence the efficiency of colony formation. Binding of a radiolabeled IL2 preparation to the in vitro activated CML cells indicated the presence of low affinity receptors for IL2. In contrast to CML, normal human marrow cells were consistently aIL2r nonreactive. Thus, IL2 receptor inducibility is a characteristic feature of CML clonogenic cells, which they share with AML, but not with normal marrow progenitors. The role of IL2 receptors in the regulation of proliferation of CML cells requires further investigation.

© *1987 by Grune & Stratton, Inc.*

INTERLEUKIN 2 (IL2) is a growth factor of T and B lymphocytes.[1-3] The expression of IL2 receptors on the surface of lymphocytic cells is a prerequisite for these cells to proliferate in response to IL2.[2,4] Recently it has been shown that receptors for IL2 can be induced on human monocytes[5,6] and acute myeloid leukemia (AML) cells[7] as well, following incubation in vitro.[6,7] Although the findings did not clarify the role of IL2 receptors in AML growth, the data suggested that these receptors may function to modulate the proliferation of human AML.

In the present studies we explored the possible presence and function of IL2 receptors in chronic myeloid leukemia (CML). We show that large proportions of CML cells from six patients, initially IL2 receptor negative, express the IL2 receptors after activation in culture. The IL2 receptor positive CML fraction contained the greatest part of the clonogenic cells, ie, CFU-GM, BFUe, and CFU-GEMM.

In contrast, normal bone marrow, including the colony forming progenitors, when treated and analyzed similarly, were consistently IL2 receptor negative. The addition of IL2 to the cultures, in doses ranging from 50 to 500 U/mL, did not modify CML colony growth and neither did blocking the IL2 receptors with an aIL2r McAb. Moreover, binding (that would have been significant for high affinity receptor presence) could not be measured with radiolabeled IL2, suggesting that most of the IL2 receptors induced on the surface of the CML cells exhibit a low affinity to the ligand.

MATERIALS AND METHODS

CML and normal bone marrow cells. CML cells were obtained from bone marrow (aspirated from the iliac spine) or peripheral blood of six patients in the first chronic phase of the disease following informed consent. The cells were separated through Ficoll-Isopaque, cryopreserved (7.5% DMSO and 20% fetal calf serum) and stored in liquid nitrogen, according to standard procedures.[8] After thawing, residual T lymphocytes were removed from the suspension with E rosette sedimentation and thus reduced to less than 1% of the nucleated cells, as previously described.[9,10] Normal marrow was obtained following informed consent from volunteers or patients without hematological disorders and prepared, and T cell depleted exactly as described for CML cells.

McAbs. The McAbs used in this study for the analysis of surface antigens are listed in Table 1.

Indirect immunofluorescence and fluorescence activated cell sorting. Cell surface membrane antigens were assayed by staining with monoclonal antibodies and goat antimouse immunoglobulins coupled to fluorescein isothiocyanate (GAM/FITC, Nordic, Tilburg, The Netherlands) as described.[16,17] The cells were then analyzed by fluorescence microscopy and by flow cytometry with a fluorescence activated cell sorter (FACS 440, Becton Dickinson, Mountain View, CA).[18]

Induction of the IL2 receptors. For induction of the IL2 receptors on the cell membrane, cells were incubated in suspension for 18 hours in the presence of phytohemagglutinin (PHA) (1% vol/vol, reagent grade; Wellcome, Dartford, England), 12-0-tetradecanoylphorbol-13-acetate (TPA) (10 μg/mL) (Sigma, St Louis) or without these additions. Subsequently, the cells were washed twice with phosphate buffered saline (PBS) and prepared for indirect immunofluorescence with the aIL2r McAb. Incubations using a McAb of the same immunoglobulin class (IgG1) (ie, OKT6 = CD1) were always included as controls. In some experiments anti IL2 receptor McAb (IgG1) + GAM/FITC stained cells were sorted and then analyzed for the expression of other surface antigens. In these experiments the sorted cells were stained with McAbs (not of the IgG1 subclass) + goat antimouse immunoglobulins, specifically reactive with the Ig class or subclass of this second antibody and coupled to the second fluorescent label tetramethylrhodamine isothiocyanate (GAM/TRITC). Analysis with McAbs of the IgG1 subclass were performed with cells previously labeled with anti-TAC McAb (IgG2a) instead

antiTac (CD25)	IgG2a	1:1,000	Anti IL2 receptor	3

of aIL2r. Cells were then evaluated for surface membrane fluorescence using a fluorescence microscope. Sorting of the cells into IL2 receptor positive and negative fractions was carried out according to previously described techniques.[18]

Myeloid colonies. CML (0.5 × 10^5 cells) or normal bone marrow (1 × 10^5) cells were plated in 35-mm Petri dishes in 0.2 mL of semisolid medium on top of a 1-mL agar (0.5%) underlayer supplemented with human placenta conditioned medium (HPCM) (30% vol/vol).[19,20] Colonies of more than 50 cells were scored on day 12 of culture. Colony counts represent the mean estimates of triplicate cultures. Colonies were collected from the dishes and examined morphologically and immunologically according to established procedures.[16]

Erythroid colonies. Erythroid colonies (BFUe) were assayed by plating 0.125 × 10^5 CML cells or 0.25 × 10^5 normal marrow cells in 0.25-mL methylcellulose cultures containing Iscove's modified Dulbecco medium supplemented with bovine serum albumin (BSA), transferrin, lecithin, natrium selenite, betamercaptoethanol, 30% fetal calf serum, and human erythropoietin derived from the urine of a patient with aplastic anemia, as described.[21] Cells (0.125 × 10^5 CML cells; 0.25 × 10^5 normal marrow) were plated in cluster dish wells and kept at 37°C and 5% CO_2 in humidified air. Cultures were performed in quadruplicate; colonies (more than 50 cells) were counted on day 14.

Mixed colonies. Mixed colonies (CFU-GEMM) were grown as described by Fauser and Messner[22] with slight modifications.[18] Colonies were scored at day 15. Mixed colonies defined as containing red hemoglobinized cells plus at least 5% nonhemoglobinized cells were always verified cytologically.

Analysis of the effects of IL2 on CFU-GM and BFUe growth. In certain experiments modifications of the standard HPCM and BFUe systems were used. HPCM cultures were performed in triplicate in 24-well dishes (Greiner, Alphen aan de Rijn, the Netherlands). Cells (0.20 × 10^5) were plated in a 100-μL semisolid upper layer on the top of a 0.25-mL underlayer. The effects of IL2 were then tested by adding IL2 to the culture upper layers (500 units/mL). Simultaneous cultures were performed to which aIL2r (2.5 μg/mL); aIL2r + IL2 (500 U/mL) or the control McAb T6(CD1; IgG1) (2.5 μg/mL) had been added. Colonies were scored on day 12. Similar experiments were carried out to examine the effects of IL2 on BFUe growth.

Binding of radiolabeled IL2. To assess the binding properties of the IL2 receptors expressed by the CML cells, we performed affinity studies with radiolabeled ^{125}I-IL2 as previously described.[23] One million cells in 50 μL alpha medium with 10% BSA were incubated with serial concentrations of pure recombinant ^{125}I-IL2 (Amersham, UK) to a final concentration of 100 pmol/L. The cells were incubated with the radiolabeled IL2 for one hour at 37°C and then radioactivity was counted in a 4/200 automatic gamma counter (Micromedic, Horsham, PA). To correct for nonspecific binding of the ^{125}I-IL2, incubations were also performed in the presence of excess nonradioactive rIL2. All incubations were carried out in duplicate.

RESULTS

Induction of IL2 membrane receptors on CML cells. Fresh CML cells (T lymphocyte depleted) did not express IL2 receptors on their surface, as indicated by the negative immunofluorescence after labeling of the cells with the McAb aIL2r. On the other hand, high reactivities of the cells with the McAb aIL2r were apparent in all six cases following incubation of the cells in suspension (18 hours) (Fig 1, Table 2). The fraction of aIL2r positive cells was estimated at 42.2 ± 19.7% (mean ± SD; range 20% to 80%; n = 6). The induced cells did not show any reactivity with a control McAb of the same isotype (ie, OKT6; IgG1). IL2 receptor positive CML cells were separated by fluorescence activated cell sorting and examined morphologically and immunologically. The IL2 receptor positive cell fraction contained mainly Sudan black positive myeloblasts (Table 2) and monocytes, and expressed the myeloid antigens reactive with the McAbs S4-7 (37%), S3-13 (8%), and Vim2 (12%). The IL2 receptor positive subset showed no reactivity with reagents recognizing the lymphocytic T3 antigen, E rosette receptor, CALLA (CD10) and B cell antigens (B4; CD19), erythrocytic antigen glycophorin A and platelet antigen glycoprotein IIIA.

In contrast to these findings with CML cells, we were consistently unable to demonstrate any expression of IL2 receptors on T cell depleted normal marrow cells (n = 14 cases), before or after incubation (Fig 1).

Colony formation by IL2 receptor expressing CML cells. Activated CML cells were sorted into IL2 receptor

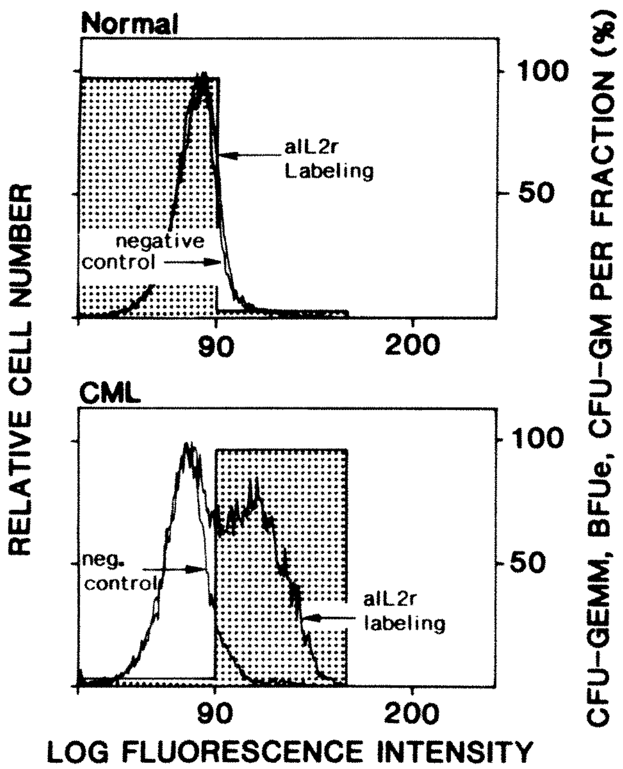

Fig 1. Fluorescence histograms indicating the IL2 membrane receptor expression on induced CML and normal bone marrow. As controls, cells were incubated with the fluorescent label but without IL2 receptor reactive McAb to assess background (negative) fluorescence. Colony-forming cells (CFU-GM, BFUe, and CFU-GEMM) were determined by sorting the cells into negative (channels 0 to 90) and positive (channels 91 to 255) fractions and the distributions are also indicated (stippled block diagrams). Two examples are given: (A) normal bone marrow (T cell depleted); and (B) CML bone marrow (T cell depleted).

positive and IL2 receptor negative fractions in three experiments and cultured for CFU-GM, BFUe, and CFU-GEMM (Table 3, Fig 1). The aIL2r positive fraction contained the majority of CFU-GM, BFUe, and CFU-GEMM. To exclude the possibility that IL2 receptor negative cells had been miscarried with the IL2 receptor positive sorts and had been responsible for colony formation, a control sort was carried out. For this purpose, the cells were stained with GAM/FITC alone and sorted on fluorescence intensity exactly as had been done with the aIL2r labeled cells. Among the so-called positive sort of the McAb unlabeled GAM-FITC labeled control, only 1% of progenitor cells were collected.

Effects of IL2 and aIL2r McAb on colony formation. The effects of r-IL2 on myeloid and erythroid colony formation by CML cells (three cases) and normal bone marrow (four cases) were examined. The addition of rIL2 (500 U/mL) did not alter the myeloid colony forming efficiency in cultures with or without colony stimulating factor, nor did it modify the plating efficiency of BFU-e (Fig 2). Moreover, IL2 alone was inactive in stimulating colony growth.

Blocking of the receptors with 2.5 μg/mL aIL2r McAb exerted no effect on CML myeloid colony growth (CFU-GM), whereas BFUe growth was slightly reduced. This inhibition of BFUe formation (due to aIL2r McAb presence in culture) could not be overcome by the concomitant addition of high concentrations of r-IL2 (500 U/mL) to the cultures (Table 4).

Table 2. Differential Count of aIL2 Receptor Positive and Negative Sorted CML Cell Fractions

Fraction	Unfractionated	aIL2r Positive
Blast cell	53.5	65.6
Promyelocyte	3.1	1.2
Myelocyte	0	0
Metamyelocyte	0	0
Neutrophil	0.2	0.4
Basophil	0	0
Eosinophil	0	0
Monocyte	25.8	20.8
Lymphocyte	2.0	0.8
Unclassified	15.3	11.2
Sudan black	ND	78%
Alpha-naphthyl-esterase	ND	0
E rosette forming	0	0

CML cells were incubated for 18 hours to induce IL2 receptor expression and then subjected to fluorescence activated cell sorting. The differential analysis was made on a total number of 500 cells. The results are expressed as percentages. ND, not done.

Binding of radiolabeled ^{125}I-IL2. To assess the binding properties of the IL2 receptors expressed by CML cells, we performed affinity studies with radiolabeled ^{125}I-IL2. Serial dilutions up to a concentration of 100 pmol/L radiolabeled IL2, which fully saturates high affinity receptors on PHA stimulated peripheral blood cells (PHA-PBL)[4] did not show any significant binding of IL2 to the induced CML cells. Only in the presence of excessive concentrations of ^{125}I-IL2 (ie, 1,500 pmol/L) was some specific binding measured. These results suggest that the IL2 receptor induced on CML cells were predominantly, if not all, of low affinity.

DISCUSSION

The regulatory role of the polypeptide hormone IL2 in the proliferation of activated T and B lymphocytes has been well established.[1,2] The use of pure radiolabeled IL2 preparations and monoclonal antibodies reactive with the surface membrane receptors for IL2 has led to a detailed insight into the inducibility and the binding characteristics of IL2 receptors on normal and neoplastic lymphoid cell types.[4,23,24] Activated T and B lymphocytes express two types of IL2 membrane receptors: one with a high affinity and another with a low affinity for the ligand.[4]

Recently, IL2 receptors have been detected on cells of nonlymphoid origin as well, ie, a subpopulation of in vitro activated peripheral blood monocytes[5,6] and also on AML cells of diverse FAB types in nearly all patients investigated.[7] This raised the intriguing possibility that IL2 receptors also have a regulatory role in the proliferation of AML cell growth. In the present report we demonstrate that IL2 receptors can be induced on a majority of CML (chronic phase) cells during incubation in suspension.

The induction of the IL2 receptors on the CML cells did

Table 3. Numbers of CFU-GM, BFUe, and CFU-GEMM in IL2 Receptor Negative and Positive Cell Fractions of CML Cells and Normal Marrow

Sorted Fractions	Nucleated Cells ($\times 10^5$)	Nucleated Cells %	CFU-GM	BFUe	CFU-GEMM
Patient No. 1 (BM)					
Unfractionated	1	(100)	481	464	41
aIL2r negative	0.497	(49.7)	10	15	0
aIL2r positive	0.503	(50.3)	769	592	24
Patient No. 2 (BL)					
Unfractionated	1	(100)	704	319	47
aIL2r negative	0.586	(58.6)	139	97	58
aIL2r positive	0.414	(41.4)	747	873	116
Patient No. 3 (BL)					
Unfractionated	1	(100)	236	651	72
aIL2r negative	0.724	(72.4)	113	581	29

aIL2r positive	0.106	(10.6)	4	35	ND

Cells of three CML patients and two normal subjects were first T cell depleted, then stained with the McAb aIL2r and GAM/FITC and sorted into negative (channels 1 to 90) and positive (channels 91 to 255) fluorescent populations. The fractions were cultured to assess the number of hemopoietic progenitors. Colony forming cells are expressed as absolute numbers.

Abbreviations: BM, bone marrow; PB, peripheral blood; ND, not done.

not require specific activating agents such as the lectin PHA or the phorbol ester TPA. This is a property that CML cells share with certain cases of AML, but which distinguishes them from T and B lymphocytes.[1,2,7] Frequently, IL2 receptor positivity appeared following incubation in medium not supplemented with inducers. Separation of IL2 receptor positive and negative cells and their subsequent incubation in colony assays revealed that the majority of the hemopoietic progenitors (CFU-GM, BFUe, CFU-GEMM) express IL2 receptors after induction (Table 3). Morphological analysis showed that the aIL2r positive fractions mainly contained immature cells (blasts) and monocytes.

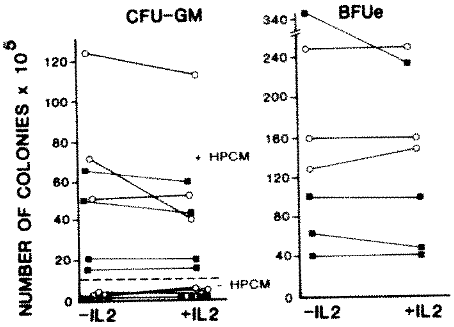

Fig 2. Effect of IL2 on CML and normal marrow colony formation in vitro (CFU-GM, BFUe). + IL2, 500 U/mL IL2 added to the cultures; −IL2, no IL2 added; + HPCM, CFU-GM grown in an assay supplemented with 30% HPCM as the source of colony stimulating factor; −HPCM, no HPCM added. ○, CML (three cases); ■, normal bone marrow (four cases). On the Y axis the number of colonies per 10^5 cells (unfractionated) are plotted.

Table 4. Effect of IL2 Receptor Blocking on CML Colony Growth

	Numbers of CFU-GM (per 10^5 Cells; %) Case 1	Case 2	Case 3
Cultures without addition*	52 (100%)	125 (100%)	71 (100%)
Cultures with aIL2r McAb† (receptor blocking)	133%	89%	70%
Cultures with T6 McAb‡ (no receptor blocking)	107%	88%	65%
	Numbers of BFUe (per 10^5 Cells; %)		
Cultures without addition*	160 (100%)	151 (100%)	285 (100%)
Cultures with aIL2r McAb† (receptor blocking)	37%	27%	30%
Cultures with T6 McAb‡ (no receptor blocking)	70%	74%	81%

The addition of recombinant IL2 (in doses ranging from 50 to 500 U/mL) concomitantly with the aIL2r produced no effect.

*Colonies in nonsupplemented cultures are expressed as mean numbers per 10^5 cells (triplicate cultures) and set at 100%.

†Anti IL2 receptor McAb (2.5 μg/mL) was added to the cultures and colony numbers expressed as percentage of control values (without addition).

‡Control McAb of the same Ig subclass (T6, IgG1) (2.5 μg/mL) was added to the cultures and colony numbers expressed as percentage of data from cultures without addition.

It is noteworthy that the sum of the recoveries of the colony-forming cells from the IL2 receptor positive and negative fractions exceeded the total numbers of the unfractioned cell samples. This was true for CFU-GM and BFUe in all CML experiments and for CFU-GEMM in two of three experiments. The reason for the higher colony forming cell yields following cell separation has not been investigated, but could relate to the removal of inhibiting accessory cells from the IL2 receptor positive cell fraction. Support for this explanation comes, for instance, from cell separation studies on CFU-GEMM, BFUe, and CFU-GM, in which the removal of T cells and mature myeloid cells resulted in increased cloning efficiencies and elevated recoveries of hemopoietic progenitors.[25,26] The presence of IL2 receptors on a large portion of CML cells and particularly CML progenitors suggests a possible role for these receptors in cell proliferation. Normal bone marrow cells and progenitors completely lacked the capacity to express IL2 receptors under identical experimental conditions. The absence of IL2 receptors on normal hemopoietic precursor cells, on one hand, and their expression on human AML and CML cells, on the other, would then suggest this phenotypic trait to be specifically related to the transformed status of the myeloid cells.

Colony cultures for myeloid and erythroid precursors did not provide evidence for a function of IL2 as a growth factor in CML. The colony-forming efficiency of CFU-GM and BFUe in CML was essentially unchanged upon addition of IL2 under various conditions. Blocking the receptors with a IL2r McAb at a concentration that does suppress T cell, and B cell[24] colony growth did not exert any inhibitory effect on CML myeloid colony formation. Although a slight reduction of BFUe growth was observed in the presence of the blocking aIL2r McAb, this suppression was not reversed by adding high concentrations of IL2 (competing with the McAb for receptor binding) concomitantly to the cultures. Thus these studies do not provide positive indications for a functional role of IL2 receptors in CML cell proliferation. The fact that colony growth was not modified following exposure of the cells to rIL2 or to aIL2r could be in good agreement with the findings that virtually no high affinity receptors for IL2 were detectable on the CML cells. The question why IL2 receptors are typically inducible on AML cells and on CML hemopoietic progenitors but not on normal bone marrow (precursor) cells is intriguing. For the time being, their potential pathophysiological role remains uncertain and requires further investigation. In future experiments the question should be addressed as to whether the IL2 receptors on CML cells are structurally of low affinity and whether certain in vitro conditions (eg, prestimulation with special growth factors) will permit their conversion to high affinity receptors. In the latter case, it will be of interest to further investigate the regulatory role of IL2 on the proliferation of CML clonogenic cells, in association with that of other stimuli.

ACKNOWLEDGMENT

The expert technical assistance of Mieke Berends, Lianne Broeders, Loes van Eyck, Marius van der Haven, and Hans Hoogerbrugge is highly appreciated. We thank M. Slotboom and A. Sugiarsi for typing the manuscript. Highly purified recombinant IL2 with a specific activity of 1.9 × 10^6 U/mg protein was a gift from Biogen SA, Geneva.

The Isolation of Human Platelet Factor V

By Robert W. Viskup, Paula B. Tracy, and Kenneth G. Mann

Human platelet factor V has been isolated using either a monoclonal or polyclonal antibody directed against human plasma factor V. The largest peptide observed upon sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) analysis of purified human platelet factor V comigrates with purified human plasma factor V. However, a significant portion of the isolated protein is represented by peptides of lower apparent molecular weight (M_r). These lower M_r species that copurify with platelet factor V have been shown to be platelet factor V components by their immunological cross-reactivity with monoclonal and polyclonal antibodies to purified human plasma factor V. Platelets isolated from whole blood drawn directly into inhibitors to prevent proteolysis and platelet activation demonstrate the pattern of fragmented platelet factor V. The components of purified platelet factor V demonstrate apparent M_r ranging between 115 K and 330 K and are detectably different from the intermediates and end products observed during the thrombin cleavage of single-chain plasma factor V. Upon treatment with thrombin the platelet factor V components are cleaved and the end products are indistinguishable from those obtained upon thrombin activation of plasma factor V to plasma factor Va. Examination of the components by immunoblotting demonstrates that some of the cleavages which have occurred in the platelet factor V molecule are within the 150-K activation peptide. Bioassay indicates that platelet factor V exists as a procofactor and cleavage by thrombin yields the active cofactor, platelet factor Va. These data suggest that human platelet factor V is stored in the platelet as a partially fragmented procofactor that can be activated by thrombin to yield human platelet factor Va, the active cofactor in the human prothrombinase complex.

© 1987 by Grune & Stratton, Inc.

FACTOR V is a single-chain high–molecular weight (M_r) plasma protein that is cleaved by thrombin to yield factor Va, the activated form of factor V. Factor V/Va has been shown to play an essential role in blood coagulation by its involvement in the prothrombinase complex that consists of factor Va, factor Xa, an appropriate membrane surface, and divalent metal ions.[1-4] Although factor Xa alone can catalyze the cleavage of prothrombin to thrombin in solution, its incorporation into the prothrombinase complex yields an increase of 278,000-fold in the rate of thrombin generation.[5] In vitro, phospholipid vesicles have been utilized as the surface which accelerates the conversion of prothrombin to thrombin catalyzed by prothrombinase,[5-7] whereas in vivo the platelet membrane is one surface where assembly likely takes place.[8-12]

Plasma factor V/Va has been shown to be produced by perfused rat liver.[13-15] Recently, our laboratory has demonstrated the de novo synthesis of factor V/Va in bovine aortic endothelium.[16] Chiu et al[17] have reported its production in guinea pig megakaryocytes and Wilson et al[18] have shown it to be synthesized in a human hepatocarcinoma cell line, Hep G2. The presence of factor V antigen in human megakaryocytes,[19] platelets,[19,20] monocytes,[21] and lymphocytes[21] has been reported. Approximately 18% to 25% of the human factor V/Va found in whole blood is contained within the platelet.[20] Platelet factor V is released from the platelet upon activation by thrombin, although the amount of platelet factor V/Va released is not sufficient to saturate the platelet with respect to its prothrombinase activity.[12]

Morrison has reported that plasma factor Va may not be used in the platelet-dependent activation of prothrombin in plasma.[22] Recent work by this laboratory[23] indicates that the platelet provides an important pool of factor V/Va for in vivo prothrombinase complex activity. We have identified a family with an inherited bleeding disorder, Factor V Quebec. The only functional abnormality evident was inactive platelet factor V. Even though prothrombinase complex assembly and activity was completely normal in the presence of added purified clotting factors, this family exhibited a severe bleeding disorder. This not only points out the importance of platelet factor V in the hemostatic process but also raises the possibility that platelet factor V may be a different gene transcription product from plasma factor V. Another observation that demonstrates the importance of platelet factor V in hemostasis has been reported by Nesheim et al.[24] In this instance a plasma factor V inhibitor reduced plasma factor V activity to <1% of normal. Despite this apparent compromise of the hemostatic system, the subject did not bleed abnormally following surgical challenge. Normal platelets isolated from whole blood to which the purified antihuman factor V antibody had been added demonstrated no effect from exposure to the inhibitory antibody. These platelets, upon thrombin stimulation, supported normal prothrombinase activity in the presence of exogenously added factor Xa and the inhibitor. This implies that the platelet factor V was protected from the inhibitory antibody and again implicates platelet factor V as playing a very important role in hemostasis. This recent evidence points to the possibility that even though platelet factor V is not the major pool of factor V present in the circulation, it may be the important species in vivo. We have undertaken this study to isolate and examine human platelet factor V.

100, and bovine albumin (essentially fatty acid free) (BSA) were purchased from Sigma, St Louis. Benzamidine HCl was obtained from Aldrich, Milwaukee; polyethylene glycol (PEG) 8,000 was from J.T. Baker Chemical, Phillipsburg, NJ; Iodogen was from Pierce, Rockford, IL; sodium heparin (from beef lung, 10,000 USP units/mL) was from Organon, W Orange, NJ; rabbit antimouse IgG was from Cappel, Cochranville, PA; and normal mouse sera was from Pel-Freeze, Rogers, AR. QAE-cellulose was purchaed from Schleicher and Schuell, Keene, NH. All other reagents were of the highest analytical grade available.

Proteins. Homogenous, single-chain human factor V was prepared utilizing a hybridoma antibody as previously described by Katzmann et al[25] with modifications as described by Litwiller et al.[26] Factor Va was prepared by the incubation of factor V with catalytic amounts of thrombin.[27] Bovine thrombin was prepared as described by Lundblad et al.[28]

^{125}I-Protein A and ^{125}I-rabbit antimouse IgG were prepared by the Chloramine T method[29] or Iodogen.[30] The radiolabeled proteins were separated from the other iodination products by chromatography on G-25 Sephadex. Mouse ascites were used as the source of murine monoclonal antibody directed against human plasma factor V. This antibody, designated αHFV-7, has been previously characterized by Foster et al[31] and was shown to react with human plasma factor V but not human plasma factor Va. Recent work has shown that the epitope is contained within the activation peptide of M_r 150,000 that has been designated component C1, using the nomenclature suggested by Nesheim et al[32] for bovine factor V.

A polyclonal antibody directed against human plasma factor V/Va was obtained from burro antisera previously described by Tracy et al.[20] IgG was prepared by precipitation with solid ammonium sulfate to 35% saturation followed by chromatography on DEAE-cellulose (10 mmol/L Tris, 40 mmol/L NaCl, pH 8.5). Normal burro IgG was purified in the same manner. These partially purified IgG fractions were subsequently used for immunoblotting. IgG specific for human plasma factor V was purified from the burro polyclonal antibody as described by Nesheim et al[24] and covalently coupled to Sepharose to yield an antihuman plasma factor V immunoabsorbant. Briefly, partially purified burro polyclonal antihuman plasma factor V IgG was applied to a human plasma factor V-Sepharose column and the bound material (specific antihuman factor V IgG) was eluted with 3 mol/L NaSCN. The fractions containing factor V inhibitory activity were pooled, concentrated, and covalently coupled to CH-Sepharose 4B to yield a specific polyclonal antihuman plasma factor V immunoabsorbant to be subsequently utilized for the purification of platelet factor V. A nonimmune Sepharose column was also prepared by coupling normal burro IgG to CH-Sepharose 4B and was used as a control immunoaffinity column.

Factor V bioassay. A two-stage bioassay was used as previously described by Nesheim et al[27] using human factor V–deficient plasma prepared by immunoabsorption of whole plasma on antihuman factor V-Sepharose.[25] Factor V activity was determined by comparing the clot times with those obtained from a standard curve using a normal human plasma pool as the source of factor V. The ratio of the measured factor V activity after and before the intentional activation by thrombin is termed the activation quotient and provides an estimate of the degree to which the factor V sample has been unintentionally activated. Activation quotients of greater than 20 usually indicate a relatively minor amount of unintentionally activated factor V in the sample.

Platelet isolation. Fresh platelet rich plasma (PRP) was obtained from the American Red Cross Blood Center, Burlington, VT. Within approximately 25 minutes after beginning the phlebotomy, an inhibitor cocktail was added to the PRP (1 vol of inhibitor cocktail: 29 vol PRP) such that the final concentration of inhibitors was as follows: 5 mmol/L EDTA, 3.3 mmol/L benzamidine, 1 mmol/L ε-ACA, 20 μg/mL STI, 10 μmol/L PMSF, 2 U/mL heparin, 2.5 μmol/L PGE_1, and 2 mmol/L NEM. Diisopropyl fluorophosphate was subsequently added to a final concentration of 1 mmol/L. All subsequent steps were performed at room temperature using polypropylene tubes and pipettes. The PRP containing inhibitors was centrifuged at 190 × g for 15 minutes to remove red blood cell contamination evident in some of the Red Cross PRP. The PRP was then centrifuged at 1000 × g for 15 minutes to yield platelet poor plasma (PPP) and a platelet pellet. The platelet pellet was gently resuspended using a polypropylene pipette to approximately 40% of the original volume of PRP in Orloff and Michaeli wash buffer (0.127 mol/L NaCl, 4 mmol/L KCl, 30 mmol/L glucose, 10 mmol/L NaH_2PO_4, and 0.35% BSA)[33] containing the inhibitors. The resuspended platelets were washed three times. Platelets were also isolated from blood drawn directly into inhibitors. Approximately 30 mL of blood was drawn using a 19-gauge infusion set directly into a syringe containing anticoagulant (1 vol acid-citrate-dextrose: 6 vol blood) and protease inhibitors as described above. The platelets were then isolated as previously described. Blood was also drawn and allowed to clot to yield normal serum. All blood collection accomplished for this research was reviewed and approved by the Vermont Human Studies Committee.

Isolation of platelet factor V. Washed platelets were resuspended to approximately 4×10^9 platelets/mL in Orloff and Michaeli wash buffer containing inhibitors but not BSA. In addition, leupeptin and DFP were added to final concentrations of 0.5 mmol/L and 1 mmol/L, respectively. All platelet counts were performed using a ZM Coulter Counter (Coulter Electronics, Hialeah, FL).

Platelet lysates were prepared by the addition of Triton X-100 to a final concentration of 1% (vol/vol) followed by sonication. The sonication was repeated three times with one minute of sonication on ice followed by two minutes of cooling. The platelet lysate was then centrifuged at 18,000 × g for 20 minutes at 4°C. To the supernatant, which contained platelet factor V, an equal volume of buffer (25 mmol/L Tris-HCl, 5 mmol/L $CaCl_2$, 1 mmol/L benzamidine, pH 7.5), an equal volume of cold H_2O, and a small amount of washed QAE-cellulose (~10 mL) were added as previously described for the purification of bovine and human plasma factor V.[25,27] The mixture was stirred in the cold for 30 minutes. The platelet factor V bound to the QAE-cellulose was eluted as previously described.[25,27] The fractions containing platelet factor V activity were pooled and applied to a nonimmune burro IgG Sepharose column (~2 mL bed volume, prepared as described) equilibrated with 0.3 mol/L NaCl, 20 mmol/L imidazole, 5 mmol/L $CaCl_2$, 1 mmol/L benzamidine, pH 6.5). The flowthrough from the nonimmune burro IgG Sepharose column containing the platelet factor V activity was immediately applied to the specific burro polyclonal antihuman factor V immunoabsorbant (~2 mL bed volume, prepared as described) equilibrated in the same buffer as the nonimmune column. The column was then washed until the A_{280} reached baseline. The specific burro polyclonal antihuman factor V immunoabsorbant column was then washed with a minimum of 4 column volumes of 1.0 mol/L NaCl, 20 mmol/L imidazole, 5 mmol/L $CaCl_2$; 1 mmol/L benzamidine, pH 6.5, to remove nonspecifically bound protein. The absorbance of the eluant was monitored. After it reached baseline the bound human platelet factor V was eluted with 4 column volumes of 3 mol/L NaSCN, Tris-Saline, pH 7.4. The eluted human platelet factor V was dialyzed versus 0.2 mol/L acetic acid and lyophilized to dryness. Washed platelets were also lysed by the addition of 10% hot sodium dodecyl sulfate (1 vol SDS:1 vol platelets) or made 50% in acetic acid, lyophilized, and subsequently subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) followed by immunoblotting.

Immunoblotting. After SDS-PAGE on Laemmli 5% to 15% slab gels,[34] immunoblotting was performed as described by Towbin et al.[35] Transfer of the proteins from the polyacrylamide gel onto the nitrocellulose was accomplished using 100 volts for five hours in a Transphor (Hoefer, San Francisco, CA), using cooling coils to keep the temperature of the buffer at approximately 8°C. After transfer, the nitrocellulose sheets were placed into 0.15 mol/L NaCl, 20 mmol/L Tris-HCl, pH 7.4 (Tris-Saline), containing 1% BSA and 0.002% thimerosal to block nonspecific binding. Following transfer, the polyacrylamide gels were stained with Coomassie brilliant blue R to check for the completeness of transfer. Prestained high-M_r standards were used to assist in visualizing the completeness of transfer and to allow calculation of the molecular weight of proteins on the nitrocellulose.

Human plasma and platelet factor V/Va were visualized on the nitrocellulose by incubating the nitrocellulose with a primary antibody (burro polyclonal antihuman plasma factor V or a murine monoclonal directed against human plasma factor V), followed by washing and incubation with either ^{125}I-Protein A (used to visualized burro IgG) or ^{125}I-rabbit antimouse IgG (used to visualize murine monoclonal IgG). Control immunoblots were performed using nonimmune burro IgG or normal mouse serum followed by the appropriately radiolabeled protein. The unbound radiolabel was then washed off and the dried nitrocellulose subjected to autoradiography at −70°C using Kodak (Rochester, NY) XAR-5 film with DuPont (Wilmington, DE) Cronex Lightning Plus intensifying screens. All primary antibodies and radiolabeled proteins were added in Tris-Saline, pH 7.4, containing 1% BSA and 0.002% thimerosal for three hours at room temperature. The washing consisted of one 10-minute wash with Tris-Saline, pH 7.4; one 20-minute wash with Tris-Saline, pH 7.4, containing 0.05% NP-40; and a 10-minute wash with Tris-Saline, pH 7.4.

RESULTS

Chromatographic identity of human platelet and plasma factor V. It has been shown previously using radioimmunoassay that the burro antihuman factor V antibody recognizes both human plasma and platelet factor V/Va and exhibits no cross-reactivity with other plasma proteins.[20] Therefore, for the purification of human platelet factor V, conditions similar to those used for the purification of human plasma factor V were employed. Platelet lysate containing platelet factor V and PPP containing plasma factor V were isolated from PRP obtained from the American Red Cross to which inhibitors had been added as described. The plasma from the PRP was treated with $BaCl_2$ and PEG 8,000 as previously described for the purification of bovine and human plasma factor V.[25,27] Both the plasma and platelet lysate were individually batch-absorbed to QAE-cellulose and subsequently eluted by the stepwise addition of 20 mmol/L imidazole, 5 mmol/L $CaCl_2$, 1 mmol/L benzamidine, pH 6.5, containing (*a*) no NaCl, (*b*) 0.1 mol/L NaCl, and (*c*) 0.3 mol/L NaCl.[25,27] The eluates were assayed for factor V activity and both the platelet and plasma factor V activity were eluted in step (*c*) above. The fractions containing either platelet or plasma factor V activity were concentrated by precipitation to 70% saturation with $(NH_4)_2SO_4$ and redissolved in Tris-Saline, 5 mmol/L $CaCl_2$, pH 7.4. Both were diluted so the activity per milliliter was identical (6 units/mL). Approximately 12 units of platelet or plasma factor V activity were applied to a 1-ml bed-volume murine monoclonal antihuman factor V immunoabsorbent column routinely used for plasma factor V purification.[25] The platelet or plasma factor V activity was retained by the column. The column was then washed and the bound plasma or platelet factor V activity was then eluted with 1.75 mol/L NaCl, 20 mmol/L Tris-HCl, 5 mmol/L $CaCl_2$, pH 7.4. Similar recoveries of the pooled peaks of plasma factor V activity (47%) and of the platelet factor V activity (49%) were observed as determined by factor V bioassay. When the 0.3-mol/L NaCl eluates from the QAE-cellulose chromatography step containing either platelet or plasma factor V activity were applied to a nonimmune burro IgG Sepharose column used as a control, the factor V activity was not retained and was recovered in the column flowthrough. The application of partially purified platelet or plasma factor V to the specific burro antihuman factor V Sepharose column also resulted in the binding of both factor V species. Since elution from the polyclonal antibody column was accomplished with 3 mol/L NaSCN and Tris-Saline, pH 7.4, the bioactivity of the eluates from the specific burro antihuman factor V Sepharose column could not be determined.

Purified human platelet factor V. Preliminary studies of human platelet factor V in platelet lysates demonstrated multiple bands when immunoblotted with the burro antihuman factor V antibody. Immunoaffinity chromatography using a monoclonal antibody directed to a single epitope would selectively yield single-chain factor V and the limited number of fragments bearing the relevant epitope. The specific burro antihuman factor V antibody coupled to Sepharose was used to isolate platelet factor V in order to maximize the number of fragments purified. Table 1 shows three typical purifications of human platelet factor V after elution from QAE-cellulose. The activation quotient is approximately 20, indicating that the platelet factor V is activated by thrombin to platelet factor Va. This suggests that platelet factor V is stored as the procofactor and thrombin is able to activate the procofactor to platelet factor Va, the active cofactor in the prothrombinase complex.

Figure 1 is a diagrammatic representation of the postulated intermediates and end products of the thrombin cleavage of human plasma factor V observed in our laboratory.[25] The nomenclature is that used by Nesheim et al[32] for the cleavage pattern observed with bovine plasma factor V. This nomenclature will be utilized in referring to the human plasma factor V components. The apparent M_r are those determined by this laboratory for human factor V/Va.[25] An M_r of 150,000 was assigned to human activation peptide C1 as this species demonstrates an increased M_r on polyacrylamide gels when compared to the bovine fragment C1.

Table 1. Purification of Human Platelet Factor V from QAE-Cellulose

Platelet Preparation	A_{280}	Total Activity* (Units)	Specific Activity (Units/A_{280})	Activation Quotient†
1	29.0	91	3.14	26
2	26.8	84	3.13	21
3	32.2	129	4.01	18

*Activity was measured with factor V-deficient plasma after activation by thrombin.

†Ratio of activity after and before activation. Platelet lysate was batch-absorbed as described and the platelet factor V activity eluted with 0.3 mol/L NaCl, 20 mmol/L imidazole, 5 mmol/L, $CaCl_2$, 1 mmol/L benzamidine, pH 6.5.

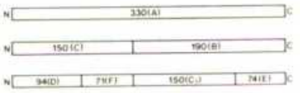

Fig 1. A model of the proposed major intermediates and end products of thrombin-catalyzed activation of human plasma factor V. The nomenclature and sequence alignment are taken from that used previously for bovine plasma factor V,[32] and the molecular weights are those determined by this laboratory for human plasma factor V and its thrombin-catalyzed cleavage products.[25]

Components D and E are assigned the same M_r as their bovine counterparts. Even though the human NH_2 terminal component D demonstrates an M_r of greater than 94,000 on reduced SDS-PAGE, preliminary determinations using analytical ultracentrifugation gives an M_r of approximately 94,000 for human component D (Jenny and Mann, unpublished data).

Figure 2A illustrates an immunoblot of purified human plasma factor V, purified human plasma factor V activated with thrombin, and three different preparations of purified human platelet factor V. The primary antibody was burro antihuman factor V, which recognizes both human plasma factor V, factor Va, and the factor V fragments. The purified human platelet factor V lanes reveal numerous components. The largest molecular weight component comigrates with purified plasma factor V (M_r 330,000). However, the lower-M_r components do not correlate with any of the thrombin or factor Xa activation intermediates[36] or with products of cleaved human plasma factor V/Va. The band at M_r 190,000 is slightly smaller than component B and the two bands migrating with M_r similar to component C1 (155,000 and 140,000) are slightly larger and smaller, respectively, than component C1.

Quantitative immunoblot analysis of the band intensities can be misleading due to the fact that when immunoblotting with a polyclonal antibody, some of the lower-M_r forms of factor V may be recognized more easily than the intact single-chain molecule, making the low-M_r components appear to constitute a disproportionately larger percentage of the total. Also, as ^{125}I-Protein A or ^{125}I-rabbit antimouse IgG was used to visualize the immunoblots, some of the components which exist at the highest concentration would relatively overexpose the film so that the minor bands could be visualized. This would cause a minor component to appear to constitute a larger percentage than it actually does.

Figure 2B represents an immunoblot of the same samples; however, for this analysis the primary antibody was a murine monoclonal antibody against human plasma factor V (αHFV-7) which has been shown to recognize plasma factor V but not plasma factor Va.[31,37] From the immunoblot it is evident that this monoclonal antibody recognizes single-chain plasma factor V (M_r 330,000) and the activation fragment C1 of thrombin-activated plasma factor V. This antibody recognizes a component in purified platelet factor V which comigrates with single-chain plasma factor V (330,000), a band at 190,000, and two smaller bands at 125,000 and 115,000. Note that the two bands of 155,000 and 140,000 evident in blotting with the burro antihuman factor V antibody are not evident, demonstrating that they are not related to component C1. Immunoblotting analysis using monoclonal and polyclonal antibodies to human plasma factor V thus illustrates that factor V purified from platelets is largely fragmented.

Visualization of factor V in platelets isolated directly into inhibitors. There was an interval of approximately 25 minutes between the start of phlebotomy by the American Red Cross and the addition of the inhibitors. The presence of multiple components in the purified platelet factor V preparations indicated the existence of substantial proteolytic cleavage of the single-chain high-M_r platelet factor V molecule even in the presence of numerous inhibitors. In order to assess whether extensive proteolysis of platelet factor V might be occurring prior to the addition of inhibitors, platelets were isolated from blood drawn directly into inhibitors and the extent of proteolysis of their platelet factor V was examined.

Washed platelets from blood drawn directly into inhibitors were lysed with hot detergent (SDS) or glacial acetic acid and subjected to SDS-PAGE followed by immunoblotting. Figure 3 demonstrates that platelet factor V is fragmented, even though the blood is drawn directly into inhibitors and the inhibitors are present throughout the entire washing and lysing procedure. The fragments of platelet factor V seen in the lysed platelets are the same as the fragments seen in the purified preparations of platelet factor V. Increasing the concentration of inhibitors by an order of magnitude had no effect on the fragmentation pattern seen on the immunoblots. Plasma from the same individual shows the major species of plasma factor V being component A, intact factor V at M_r 330,000. Serum was also made at the same time with no

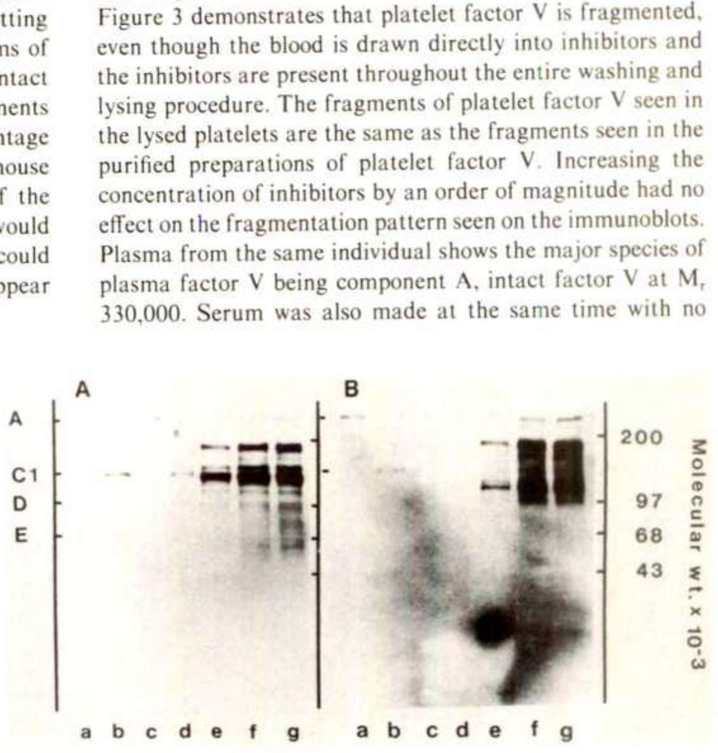

Fig 2. Immunoblot of purified human plasma and human platelet factor V. In (A) the primary antibody was burro antihuman factor V followed by ^{125}I-Protein A. The primary antibody in (B) was a murine monoclonal to human plasma factor V (αHFV-7) followed by ^{125}I-rabbit antimouse IgG. The samples in the various lanes are the same in both panels. Lanes: (a) Purified human plasma factor V, 200 ng; (b) purified human plasma factor V, 200 ng, activated with thrombin to yield human plasma factor Va and the activation peptides; (c) purified human plasma factor V, 100 ng; (d) purified human plasma factor V, 100 ng, activated with thrombin to yield human plasma factor Va and the activation peptides; and (e through g) three different preparations of purified human platelet factor V (~4 μg).

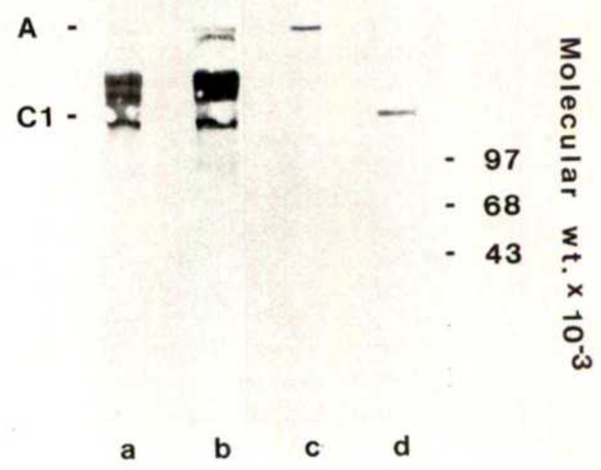

Fig 3. Immunoblot of human platelets drawn directly into protease inhibitors and washed as described. The primary antibody was burro antihuman factor V followed by ^{125}I-Protein A. Lanes: (a) human serum (7.5 μL); (b) human plasma (7.5 μL); (c) washed platelets (5 × 10^7 platelets) lysed with detergent (SDS); and (d) washed platelets (5 × 10^7 platelets) lysed with glacial acetic acid.

inhibitors present and upon immunoblotting demonstrates a band which comigrates with the major immunoblotted band evident in thrombin-activated human factor V (component C1, the large activation peptide, M_r 150,000).

The possibility that the protease inhibitors were not inhibiting the cleavage of platelet-associated factor V during the lysis of the platelets was examined. Human plasma factor V and the various thrombin generated intermediates were mixed and radioiodinated. A mixture of factor V, its high-M_r intermediates, and the factor Va subunits was chosen in order to detect proteolysis of any single component. The ^{125}I-factor V(Va) mixture was incubated with washed platelets (2 × 10^9) that were isolated and washed in the presence of the inhibitor cocktail detailed in Materials and Methods. Following the various incubations detailed below, the ^{125}I-factor V(Va) mixture and lysed platelets were subjected to SDS-PAGE followed by autoradiography. Figure 4 illustrates the results of this experiment. Lane a depicts the ^{125}I-factor V(Va) mixture added to the buffer containing inhibitors followed by the addition of an equal volume of boiling 10% SDS. Lane b depicts the same ^{125}I-factor V(Va) mixture added to washed platelets followed by the addition of an equal volume of boiling 10% SDS. Lane c depicts the lysing of platelets by boiling 10% SDS followed by the addition of the ^{125}I-factor V(Va) mixture. The ^{125}I-factor V(Va) mixture was also added to platelets and the platelets lysed by the addition of Triton X-100 to a final concentration of 1%. After five minutes (lane d), 10 minutes (lane e), and 15 minutes (lane f), the incubation was terminated by the addition of boiling SDS. There is no discernible difference in the ^{125}I-factor V(Va) mixture when added to platelets lysed with either boiling SDS or Triton X-100 followed by boiling SDS. Identical results were obtained when platelets were lysed by the addition of glacial acetic acid (50% vol/vol). These results indicate that the protease inhibitors present are inhibiting any additional cleavage of the factor V which might occur during platelet lysis.

Thrombin activation of isolated platelet factor V. The procofactor nature of the fragments seen in the platelet factor V preparation was examined. Plasma factor V is cleaved by thrombin to yield the active cofactor which functions in the prothrombinase complex, factor Va. The partially purified platelet factor V after the QAE-cellulose chromatography step demonstrated activation quotients[4] of 18 to 26 showing that platelet factor V, the procofactor, was in fact activated to Va, the cofactor, by thrombin. The ability of thrombin to cleave plasma factor V to its active cofactor is retained even when plasma factor V is bound to the monoclonal antibody column routinely used for its isolation.[31] A

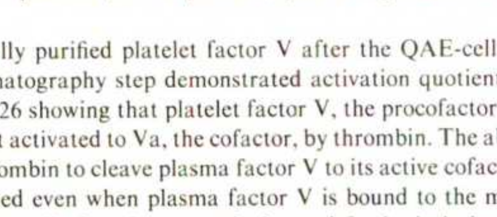

Fig 4. Autoradiography of a ^{125}I-human factor V(Va) mixture incubated with washed platelets. A mixture of ^{125}I-factor V and Va was added to washed platelets (2 × 10^9) which were collected, isolated, and resuspended in protease inhibitors. Following the protocols detailed below for each lane the ^{125}I-factor V(Va) mixture was subjected to SDS-PAGE followed by autoradiography. Lanes: (a) ^{125}I-factor V(Va) mixture plus 10% boiling SDS; (b) ^{125}I-factor V(Va) mixture and platelets followed by the addition of 10% boiling SDS to effect platelet lysis; (c) platelets plus 10% boiling SDS followed by the addition of the ^{125}I-factor V(Va) mixture; (d through f) ^{125}I-factor V(Va) mixture plus platelets which were lysed by the addition of Triton X-100 (1% final concentration) and incubated at room temperature for 5, 10, and 15 minutes respectively, prior to the addition of 10% boiling SDS.

similar approach was used to examine the activation products of platelet factor V. Following the elution of platelet factor V from QAE-cellulose with 0.3 mol/L NaCl, the preparation was then divided into two parts. Both were applied to separate specific burro antihuman factor V Sepharose columns (~1-mL bed volume, prepared as described). One column was washed and the platelet factor V eluted as the procofactor with 3 mol/L NaSCN, Tris-Saline, pH 7.4 as described. The other column was washed with 1.0 mol/L NaCl, 20 mmol/L imidazole, 5 mmol/L $CaCl_2$, 1 mmol/L benzamidine, pH 6.5 and then equilibrated with Tris-Saline, 5 mmol/L $CaCl_2$, pH 7.4. Thrombin was added to the column (3 U/mL), the flow stopped, and the column allowed to remain at room temperature for 30 minutes. The thrombin-cleaved platelet factor V was then eluted with 3 mol/L NaSCN, Tris-Saline, pH 7.4. The fractions were dialyzed v 0.2 mol/L acetic acid, lyophilyzed, and subjected to SDS-PAGE followed by immunoblotting.

Figure 5 is an immunoblot of purified human plasma factor V showing a time course of isolated human plasma factor V activated by thrombin, purified human platelet factor V, and purified human platelet factor V activated by thrombin. The lanes containing the time course of plasma factor V activation by thrombin (lanes b through e) show the disappearance of the single-chain high-M_r factor V molecule (component A, M_r 330,000); the appearance and disappearance of component B, an intermediate; and the appearance of the final end products, component C1 (M_r 150,000), the larger activation peptide, and components D and E which constitute the active cofactor, factor Va. Fragment E is hard to see in the blot because the specific burro polyclonal antihuman factor V antibody does not detect fragment E well. The lane containing purified platelet factor V (lane f) contains a component similar to component B; however, it demonstrates a slightly lower mobility. Although the appearance of component C1 is very evident in the thrombin-activated plasma factor V (lanes b through e), there is no corresponding component evident in the purified platelet factor V (lane f). The two bands migrating in that vicinity in purified platelet factor V (lane f) demonstrate M_r of 155,000 and 140,000 and are slightly larger and slightly smaller than component C1. However, when platelet factor V is treated with thrombin (lane g) a component equivalent to plasma component C1 is evident from both immunological and M_r evaluation. The purified platelet factor V (lane f) demonstrates no bands comigrating with components D and E, the two polypeptides that constitute factor Va, the active cofactor. Thrombin-activated platelet factor V (lane g) contains a platelet component D and a platelet component E. Therefore, even though the purified platelet factor V is partially fragmented, it is still activated by thrombin from the inactive procofactor to the active cofactor, platelet factor Va.

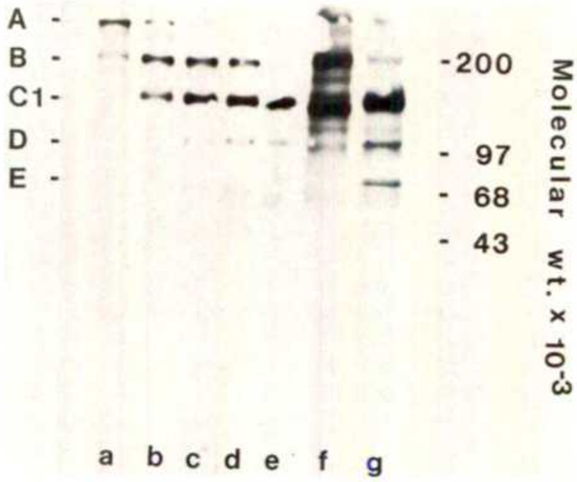

Fig 5. Immunoblot of purified human plasma factor V, purified human plasma factor V incubated with thrombin for various times, purified human platelet factor V, and purified human platelet factor V incubated with thrombin. The primary antibody was burro antihuman factor V followed by ^{125}I-Protein A. Lanes: (a) Purified human plasma factor V (650 ng); (b through e) purified human plasma factor V (650 ng) incubated with thrombin for 10 seconds; 30 seconds, 60 seconds, and 15 minutes, respectively; (f) purified platelet factor V (4 μg); and (g) purified platelet factor V (4 μg) incubated with thrombin as described.

DISCUSSION

Our results demonstrate that purified human platelet factor V can be seen to exist as a single-chain high-M_r entity that comigrates with purified human plasma factor V. Also evident are numerous components identified as arising from platelet factor V by their antigenic cross-reactivity with both polyclonal and monoclonal antibodies to human plasma factor V. Previous work by this laboratory has demonstrated immunological similarity between platelet and plasma factor V using radioimmunoassay[20] and immunofluorescent staining of human platelets and megakaryocytes.[19] Both the single-chain high-M_r human platelet factor V molecule and the lower-M_r components are recognized by thrombin and are cleaved to yield products which appear to be identical to those derived from human plasma factor V after cleavage by thrombin.

Partially purified human platelet factor V when treated with thrombin demonstrates an increased activity in the prothrombinase complex as seen by activation quotients of 18 to 26. This is equivalent to what we find for partially purified preparations of human plasma factor V, indicating that human platelet factor V exists as a procofactor. Our laboratory has observed that factor V synthesized by cultured bovine aortic endothelial cells is largely fragmented.[16] The bovine aortic endothelium factor V also exists as the procofactor, even though partially fragmented, and treatment with thrombin yields the active cofactor. Upon treatment with thrombin, the endothelial cell factor V fragments give rise to end products which appear identical to those observed upon thrombin activation of purified single-chain plasma factor V. Chiu et al[17] have recently reported the isolation of guinea pig megakaryocyte factor V. Their results indicate that guinea pig megakaryocyte factor V exists as a single-chain high molecular weight entity. We have not been able to obtain single-chain platelet factor V as a major fraction of factor V from platelets isolated from blood collected directly into inhibitors and immediately lysed with either detergent (SDS) or glacial acetic acid. These data indicate that the platelet factor V appears to be stored in platelets as a partially fragmented procofactor that can be activated by thrombin to the active cofactor, platelet factor Va. Alternatively, the platelet factor V may be partially cleaved by intracellular platelet proteases while the platelets are being collected and washed, even though protease inhibitors are present throughout the collection and wash. The inhibitors were present external to the platelet membrane during the wash, so if there is any proteolysis of platelet factor V by intracellular proteases we are unable to prevent its occurrence until after the platelets are lysed. Even platelets lysed with SDS or glacial acetic acid show that some of their platelet factor V exists as fragments. The inhibitors utilized were chosen based upon our previous experience in isolating both human and bovine plasma factor V and the recently published isolation of guinea pig megakaryocyte factor V.[17] Ethylenediamine tetraacetic acid (EDTA), NEM, and leupeptin were added to inhibit the calcium-activated neutral protease found in platelets.[38-40]

Examination of platelet factor V with an activation peptide (component C1)-specific monoclonal antibody reveals fragments of M_r >150,000 in the preparation of purified platelet factor V. Also evident are components smaller than component C1 with M_r of 125,000 and 115,000. This observation indicates that some of the cleavages of platelet factor V are occurring within the activation peptide region. This observation agrees with that of Kane et al[41] that lysed human platelets contain a protease which cleaves exogenously added human plasma factor V. They determined that some of the cleavages were occurring in the activation peptide region (fragment C1) and concluded that the activation peptide region of plasma factor V might be susceptible to proteolytic cleavage. These data correlate with the ability of partially purified platelet factor V to be activated by thrombin even though the platelet factor V has been partially cleaved.

Osterud et al[42] have previously suggested that platelets contain an enzyme which will activate platelet factor V. They also proposed that the factor V released from platelets already exists as the active cofactor, factor Va. Osterud et al[42] and Vicic et al[43] have reported that the factor V activity released after platelet lysis was not increased when incubated with thrombin, indicating that the platelet factor V existed as the cofactor, platelet factor Va. These investigators isolated platelets in the absence of protease inhibitors, and after lysing their platelets by either freeze-thawing or by the addition of Triton X-100, they saw only a slight increase in the bioassayable factor V activity after the addition of thrombin. In contrast to those data and in agreement with ours, Kane et al[41,44] and Chesney et al[45] have found that most of the platelet factor V is stored as the procofactor and the addition of thrombin causes an increase in the released platelet factor V activity. These investigators[41] have reported that the soluble fraction of platelets contains a protease that can partially activate purified factor V. They have shown that the platelet factor V released from platelets is released as the procofactor. This points out the importance of inhibiting the endogenous proteases that may act upon platelet factor V when factor V is released from the platelets or the platelets are lysed.

We have taken care to attempt to isolate and lyse our platelets in the presence of a substantial number of various protease inhibitors. Even so, our purified platelet factor V is seen to exist partially fragmented. When platelets are collected directly into inhibitors, washed, and then lysed with SDS or glacial acetic acid keeping inhibitors present throughout, the platelet factor V is still partially fragmented. Many of the cleavage products observed by Kane et al[41] appeared to be the result of peptide bond cleavage in the component C1 region of the factor V molecule. The possibility thus exists that the protease they observed may be responsible for the partial fragmentation we see in platelet factor V.

Further Studies of the Secretory Pathway in Thrombin-Stimulated Human Platelets

By James G. White and Marcy Krumwiede

The pathway followed by secretory products stored in platelet alpha granules during the release reaction remains controversial. Tannic acid has been used in the present study as an electron-dense stain to follow the secretory process in thrombin-stimulated platelets. Preliminary experiments demonstrated that tannic acid precipitates fibrinogen, and binds osmium tetroxide to fibrinogen and fibrin strands. Examination of platelets fixed at short intervals after exposure to thrombin and incubated in solutions containing tannic acid revealed electron-dense deposits of osmium not apparent in resting platelets. Granules and lumina of channels making up the open canalicular system (OCS) were unstained in discoid cells. However, exposure to thrombin at concentrations of 1 to 5 U/mL for thirty seconds or more resulted in intense staining of alpha granules by osmium. Some granules communicated directly with dilated channels of the OCS, and several were frequently connected to the same canaliculus. The electron-dense substance in swollen granules and channels appeared to be in the process of extrusion through narrow or dilated openings of the OCS onto the platelet surface. Granule-to-granule fusion and formation of sealed vacuoles of fused granule products unstained by tannic acid–osmium were not observed. The findings support the concept that secretion by stimulated human platelets results from development of direct communications between granules and channels of the OCS and subsequent extrusion of products through channel pores to the surrounding medium.

© 1987 by Grune & Stratton, Inc.

THE PROCESS OF PLATELET secretion has been a subject of interest since the release reaction was first described.[1-4] Early studies identified a system of tortuous, interconnected canaliculi in resting platelets[5,6] that appeared to serve as conduits for the discharge of storage granule products during secretion.[7,8] A simlar conclusion regarding the role of the open canalicular system (OCS) was reached in a study that demonstrated fibrin strands in the channel system of platelets activated by thrombin in the presence of EDTA.[9,10]

More recent investigations, however, have questioned the process of platelet secretion proposed in the early studies.[11-13] Ginsberg et al used immunofluorescence with monoclonal antibodies to granule products and electron microscopy to follow the secretory process in thrombin-stimulated human platelets.[12,13] Results obtained in their studies suggested that centrally concentrated granules fused together to form closed sacs that migrated to platelet surfaces, attached to the cell wall, and discharged contents to the outside. The findings appeared to confirm other work emphasizing the development of vacuoles in thrombin-stimulated platelets.[14-16] Other agents, such as phorbol myristate acetate[17] and the synthetic diglyceride, oleoylacetyl glycerol,[18] which cause secretion without platelet internal transformation, also stimulate vacuole formation in platelet cytoplasm.

Investigations of bovine platelets have also weakened arguments favoring a central role for the OCS in platelet secretion. Bovine platelets have been shown to secrete the same granule-based products as human cells.[19] However, Zucker-Franklin et al have shown that cattle platelets are virtually devoid of an open canalicular system.[20] Because of the basic similarity in the secretory response of human and bovine cells, they questioned the role of the OCS in the release reaction of either cell type.

The present study has reexamined the hypothesis that the OCS serves as the secretory pathway during the release reaction of human platelets. Tannic acid, often used as an electron dense stain,[21] was found to precipitate fibrinogen. Acting as a mordant, tannic acid selectively deposited osmic acid on fibrin and possibly other products involved in the process of extrusion from granules to channels and from the OCS through pores in the surface to the exterior of platelets stimulated by thrombin.

MATERIALS AND METHODS

General

Blood for this study was obtained from well-characterized normal donors after informed consent. Samples obtained by venipuncture were mixed immediately with citrate–citric acid–dextrose, pH 6.5 (93.0 mmol/L sodium citrate, 7.0 mmol/L citric acid, and 140 mmol/L dextrose) in a ratio of 9 parts blood to 1 part anticoagulant.[22,23] Platelet-rich plasma (C-PRP) was separated from whole blood by centrifugation at 100 g for 20 minutes at room temperature.

Preparation of Washed Platelets

Samples of C-PRP were combined with an equal volume of the citrate anticoagulant and centrifuged at 400 g for 15 minutes at 20°C to pellets.[24] Supernatant was discarded and replaced with Hank's balanced salt solution (HBSS) containing either 0.1 mol/L EDTA or adenosine (5 mmol/L) and theophylline (3 mmol/L). After 30 minutes at 37°C, the pellets were resuspended in the wash solution. The procedure was repeated twice and the platelets resuspended in HBSS with or without 0.1 mol/L EDTA at a final concentration of 5 × 10^5/mL. The washed suspensions were maintained in the 37°C water bath until used in specific experiments.

Reagents

Bovine thrombin and purified human fibrinogen were obtained from Sigma (St Louis). Reagent grade tannic acid was purchased from Mallinckrodt Chemical Company (St Louis). The reagents were dissolved in cacodylate buffer adjusted to a pH of 7.2.

Experimental Studies

Thrombin and PRP. Samples of C-PRP were fixed for study in the electron microscope before and after exposure to thrombin according to methods described previously.[25,26] Fixation was accomplished by combing the sample at the selected time with an equal volume of 0.1% glutaraldehyde in White's saline (a 10% solution of a 1:1 mixture of [a] 2.4 mmol/L NaCl, 0.1 mmol/L KCl, 46 mmol/L $MgSo_4$, 64 mmol/L $Ca(No_3)_2$, $4H_2O$ and [b] 0.13 mol/L $NaHCO_3 \cdot$ 8.4 mmol/L NaH_2PO_4 and 0.1 g/L of phenol red, pH 7.4).[27,28] After 15 minutes the samples were centrifuged to pellets and the supernatant fixative was removed and replaced with 3% glutaraldehyde in the same buffer. The samples resuspended in the second aldehyde fixative were maintained at 4°C for 30 minutes, then sedimented to pellets. Supernatant was removed and replaced with either 1% osmic acid in Zetterquist's buffer or 1% osmic acid in distilled water containing 1.5% potassium ferrocyanide for one hour at 4°C.[29]

Tannic acid has been used in our previous studies as an electron-dense stain for the open canalicular system of human platelets.[30,31] In the present study the method modified from the procedure reported by Somlyo[32] was used to stain the secretory pathway of human platelets. C-PRP and cells washed and resuspended as described above and exposed to thrombin in the presence or absence of EDTA were fixed initially with 0.2% glutaraldehyde in White's saline followed by sedimentation to a pellet, removal of the supernatant, and replacement with 3% glutaraldehyde in the same buffer for two hours at 4°C. After completion of the initial fixation steps, pellets were washed three times and stored overnight in 0.1 mol/L cacodylate buffer, pH 7.2. The buffer was decanted the following day and replaced with 2% tannic acid in 0.1 mol/L cacodylate buffer, pH 7.2 for four hours at room temperature. The supernatant was decanted, the pellets washed in cacodylate buffer and the samples postfixed in 2% osmic acid alone or combined with 1.5% potassium ferrocyanide for two hours at 4°C.

The system used in previous studies into effects of thrombin on PRP was employed in the present investigation.[25,33] Thrombin at a final concentration of 0.4 or 1.0 U/mL was combined with 1 mL of C-PRP inverted once and left in the 37°C water bath without further stirring. At intervals of 15, 30, and 45 seconds and one, three, and five minutes, samples were fixed as described above.

Thrombin and washed platelets. Suspensions of washed platelets in the presence or absence of EDTA were combined with thrombin, inverted once, and allowed to stand at 37°C without further stirring until fixed at the selected interval. Thrombin was added to 1 mL of suspension for 15, 30, and 45 seconds, and one, three, and five minutes at final concentrations of 1, 3, and 5 U/mL. Fixation was accomplished in the presence or absence of tannic acid as described above.

Tannic acid and fibrinogen. Preliminary studies into effects of thrombin on platelets in C-PRP had suggested that tannic acid acted selectively on fibrinogen and fibrin, resulting in the subsequent deposition of osmium as a dense stain. To examine this possibility, samples of platelet-poor plasma (PPP) and solutions of purified fibrinogen (250 μg/mL) were combined with equal volumes of 2% tannic acid in cacodylate buffer, pH 7.2. Precipitates that formed in both systems were fixed for study in the electron microscope. Other samples of PRP and PPP as well as solutions of fibrinogen were treated with thrombin (1 U/mL) and subsequently fixed in the presence of tannic acid as described above.

Final Preparation for Electron Microscopy

All samples were dehydrated in a graded series of alcohol and embedded in Epon 812. Thin sections cut from the plastic blocks on an ultramicrotome were examined unstained or after staining with uranyl acetate and lead citrate to enhance contrast. Examination was carried out in a Philips (Mahwah, NJ) 301 electron microscope.

RESULTS

Unstimulated Platelets Stained with Tannic Acid

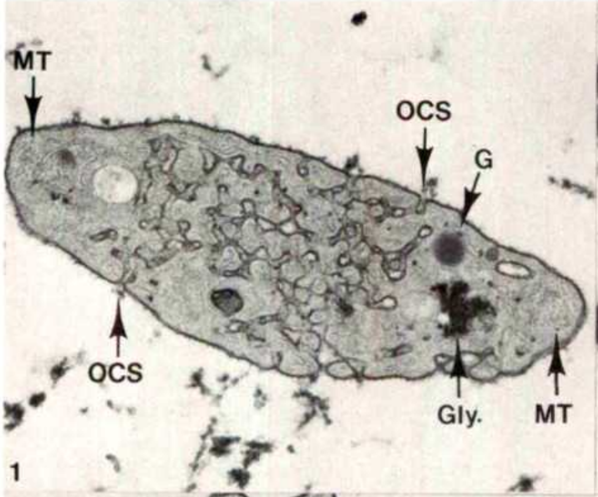
The morphology of well-preserved, resting human platelets has been described in detail in previous publications.[26-28] Resting cells have a characteristic lentiform appearance supported by a circumferential microtubule coiled under the cell surface along its greatest circumference (Fig 1). Channels of the OCS are continuous with the cell surface and form a tortuous, interconnecting lattice of canaliculi throughout the cell. Under the conditions used in this study, tannic acid combines with the exterior coat of the platelet membrane and acts as a mordant to preferentially deposit osmic acid as an electron-dense stain. As a result, the surface of the platelet and channels of the OCS are clearly delineated by dense lines. The lumina of the OCS channels are unstained in the resting platelet.

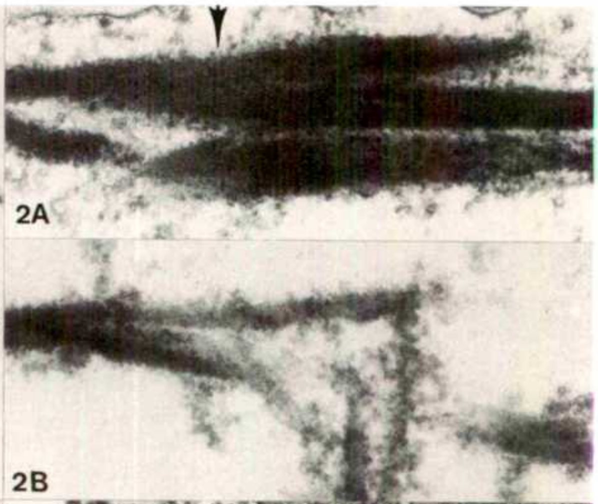
Interaction of Tannic Acid with Fibrinogen and Fibrin

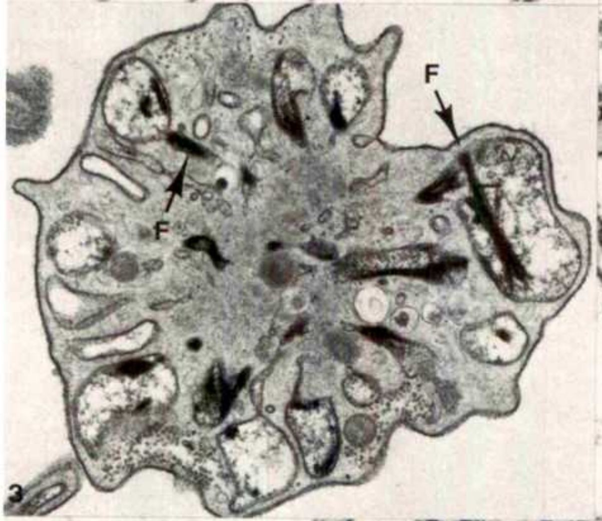
Newly formed and well-developed fibrin strands together with the heavy precipitate around and between platelets in samples of C-PRP exposed to thrombin were intensely stained by osmium (Fig 2A). This finding suggested that tannic acid might selectively, though not exclusively, react with fibrinogen and fibrin. Thin sections of tannic acid–induced precipitates formed in PPP and solutions of fibrinogen revealed intense osmium staining of amorphous and fibrillary material. Fibrin strands formed after addition of thrombin to the fibrinogen solution and subsequently stained with tannic acid during fixation revealed the same selective deposition of osmium on fibrin strands as observed in PRP and PPP (Fig 2B). Platelets from washed preparations exposed to thrombin in the presence or absence of EDTA contained fibers identical in appearance to those formed in PRP, PPP, or fibrinogen solutions in swollen granules and channels of the OCS (Fig 3).

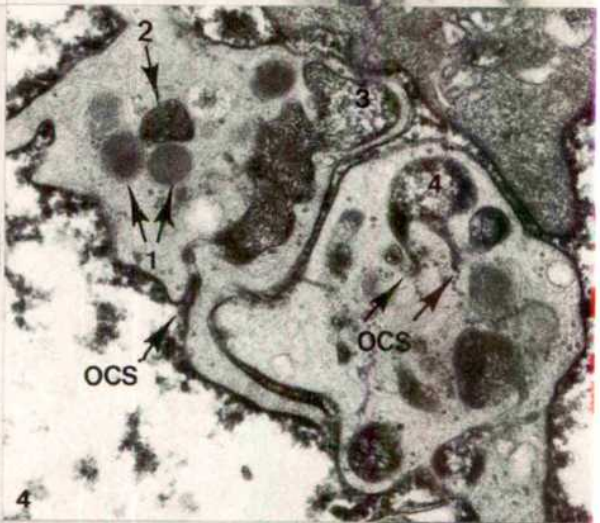
Thrombin-Stimulated Platelets

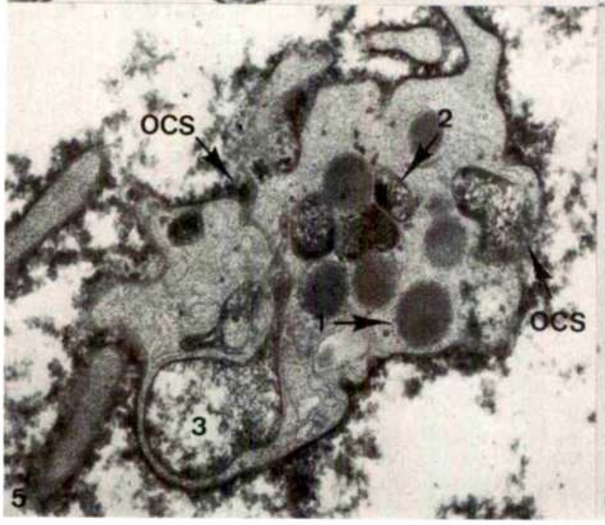
Samples of C-PRP and washed human platelets stimulated by thrombin in the presence of EDTA develop dramatic changes in their morphology. The cells lose their lentiform appearance, become irregular in form, extend numerous pseudopods, and aggregate in the absence of EDTA. At 0.4 U/mL of thrombin, platelet organelles become concentrated in cell centers and enclosed within rings of constricted microtubules. Higher concentrations of thrombin (1 U/mL) cause rapid discharge of granule contents and reduction in their number. As a result, dense spots of actomyosin in which











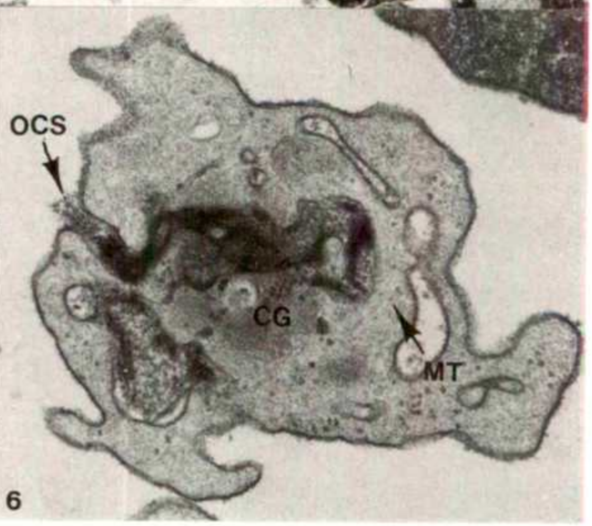


Fig 1. Cross-section of discoid platelet from sample of C-PRP stained with tannic acid (TA) during fixation with glutaraldehyde (glut) followed by osmic acid (OsA). Circular profiles of the microtubule (MT) coils supporting discoid shape are evident at each pole of the cell. Tannic acid has acted as a mordant to deposit osmic acid in the exterior coat covering the exposed surface and channels of the open canalicular system (OCS). The OCS forms a network of interconnected channels stretching from one side of the platelet to the other. Granules (G) and a mass of glycogen (Gly) particles are evident in the cytoplasm. Magnification × 20,000. Fig 2. (A) Fibrin strands in a sample of C-PRP fixed five minutes after incubation with 0.2 U/mL thrombin. Tannic acid has combined with the fibrin strands and with osmic acid, resulting in intense staining of the fibers. Typical periodic cross-striations (↑) are evident (fixation: Glut-TA-OsA). Magnification × 40,000. (B) Fibrin strands formed in sample of purified fibrinogen one minute following exposure to thrombin at 1 U/mL.

centrally concentrated organelles are enclosed in less activated platelets appear more prominent in strongly stimulated cells.

Tannic Acid Staining of Thrombin-Stimulated PRP

Tannic acid–stained platelet aggregates from C-PRP were identical in appearance to unstained control aggregates, except for the presence of osmium black precipitate. Amorphous black material surrounded the aggregates and was deposited between the cells (Figs 4 and 5). Electron-dense material was also present in normal-sized and swollen granules in many platelets. Connections between channels and granules and direct communication between canaliculi and the surrounding plasma were evident. Cytoplasmic structures including mitochondria, granules, glycogen deposits, and microtubule coils were well-preserved in the aggregated cells.

Tannic Acid Staining of EDTA Washed Platelets

Amorphous precipitate was not present outside the thrombin-activated cells from samples of washed platelets resuspended in the presence of EDTA, and aggregates were absent. The platelets, however, revealed the same physical changes observed in thrombin-aggregated cells from PRP (Figs 6 through 12). Many granules were stained intensely by tannic acid–osmium. Other granules were swollen and their content of amorphous stained material appeared diluted (Fig 8). Channels of the OCS were also delineated by electron-dense stain. Some channels were tortuous and narrow and contained little tannic acid. Others were filled by electron-dense material and widely dilated. Communications between granules and OCS channels were evident in many platelets (Figs 6 through 8, 10). The connection appeared to foster swelling of the granule and dilatation of the channel so that recognition of the site of fusion was often obscured. More than one granule was frequently in communication with the same OCS channel (Figs 7 and 8). This relationship frequently resulted in extensive dilatation of the OCS and granules fused to it. Occasionally channel openings onto the surface were dilated, but more often remained constricted as in resting platelets.

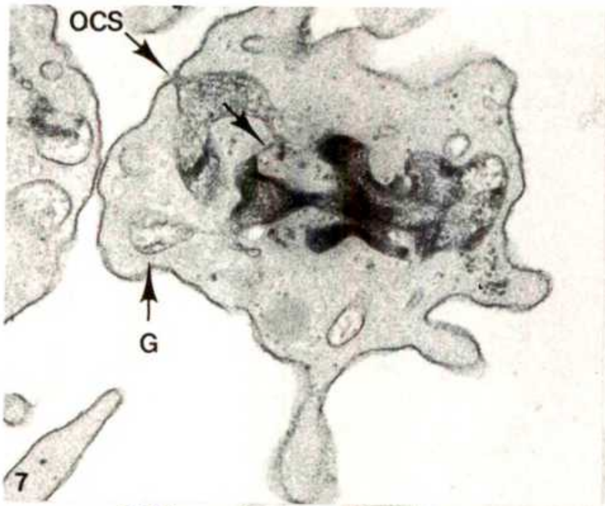
Communications between channels of the OCS and surface membrane in washed platelets exposed to thrombin in the presence of EDTA were identical in appearance to those observed in thrombin-aggregated cells from C-PRP. Some channels were dilated immediately under the cell membrane, while others remained narrow for considerable distances in the cytoplasm. Many were connected to other canaliculi and to granules. Occasionally a single channel opened in more than one place onto the surface membrane of an activated platelet (Figs 10 through 12). The electron-dense material present in channels frequently appeared to extrude into the surrounding medium. Advanced physical changes were most prominent in samples exposed to thrombin at 5 U/mL. The number of affected platelets increased between 15 and 45 seconds after exposure, but all were affected by one minute. Three units/mL of thrombin produced essentially the same results as obtained with 5 units/mL. Fewer platelets revealed the advanced changes seen with 3 and 5 U of thrombin/mL when incubated with thrombin at 1 U/mL. However, there were some, and all platelets revealed shape change and internal transformation at one minute after exposure to thrombin. Each experiment in this study has been repeated four to seven times.

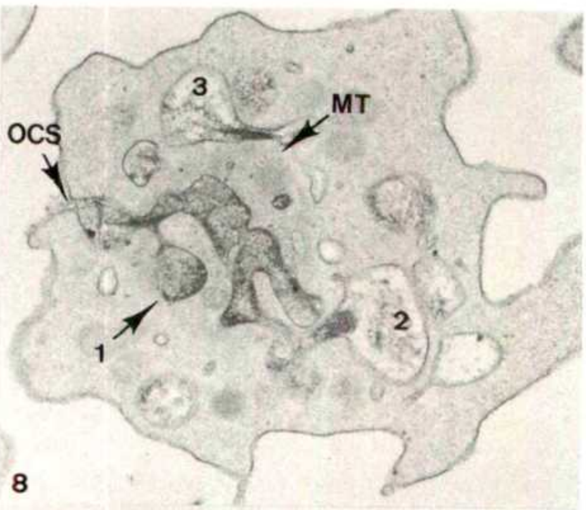
DISCUSSION

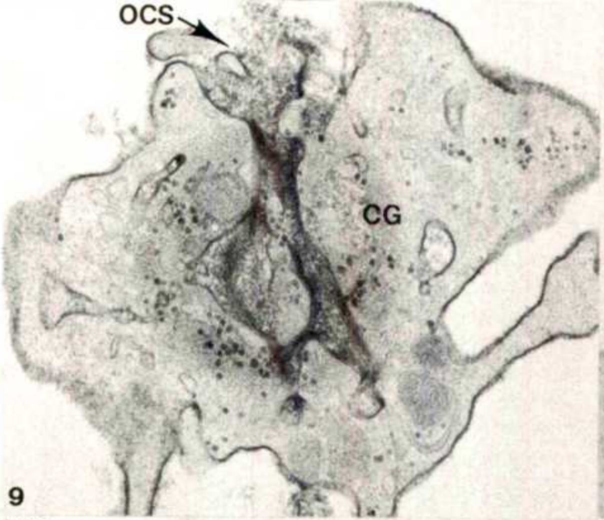
Results of the present study confirm and extend earlier work employing electron-dense tracers, which established existence of the platelet OCS and suggested its role in secretion.[5-9,34,35] In contrast to compounds used previously, tannic acid employed in the present study is not inherently electron-dense.[21,36,37] Instead, it combines with a variety of proteins, glycoproteins, complex carbohydrates, and phospholipids inside and outside of cells, and stabilizes them against extraction during fixation and dehydration.[38-41] Acting as a mordant through gallic acid groups on the molecule, tannic acid selectively deposits osmic acid on chemical or physical substances to which it has attached.[42,43] Cells are ordinarily impermeable to tannic acid, but it may enter the cytoplasm during fixation when detergents are combined with glutaraldehyde.[44] Since its introduction to electron microscopic studies, tannic acid has been used extensively to enhance the contrast of cell membranes and channels connected to the surface, as well as microtubules and microfilaments inside permeabilized cells.[39,40,45,46]

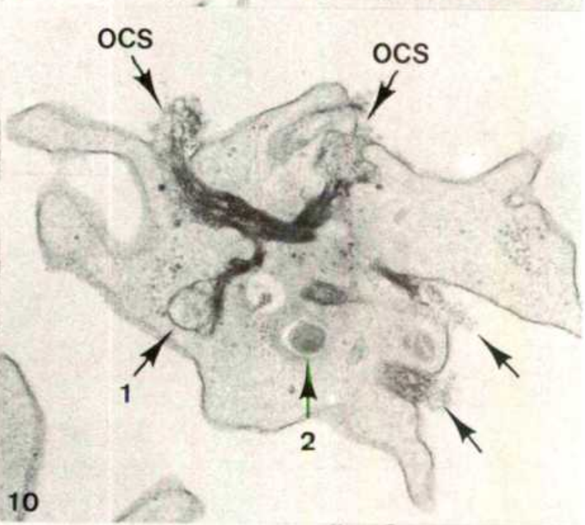
During the course of experiments on platelet clots,[47] it became apparent that tannic acid reacted with fibrin strands

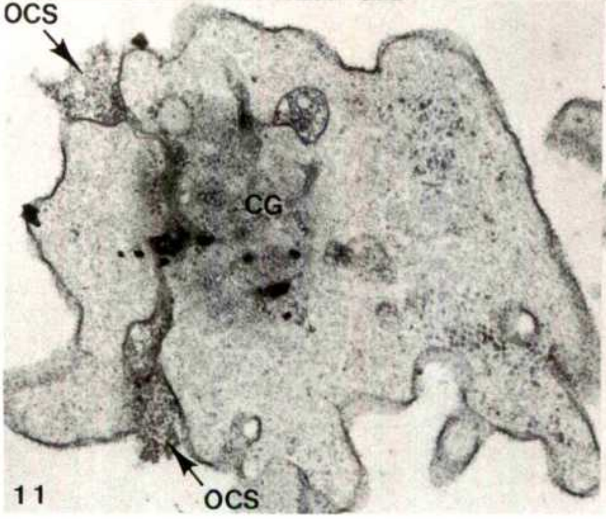
Tannic acid has resulted in heavy staining of the fibers by osmic acid (fixation: Glut-TA-OsA). Magnification × 33,000. Fig 3. Platelet from a washed suspension exposed to 5 U/mL of thrombin for three minutes and fixed in solutions containing tannic acid. Intensely stained fibers (F) identical to fibrin strands formed in C-PRP and fibrinogen solutions exposed to thrombin and stained with tannic acid were evident in swollen granules and channels of the OCS (fixation: Glut-TA-OsA). Magnification × 17,000. Fig 4. Platelet aggregate from sample of C-PRP exposed to 1 U/mL of thrombin for three minutes. Clumps of tannic acid–osmium stained fibrinogen are evident around and between the aggregated cells. Some granules (1) are unstained while others (2) show a strong reaction. Another granule (3) communicates through dilated and narrow segments of the OCS with the surface membrane on the other side of the platelet. A fourth granule (4) appears to communicate with two segments of the OCS in an adjacent platelet (fixation: Glut-TA-OsA). Magnification × 25,000. Fig 5. Platelet from the same sample of aggregated platelets shown in Fig 4. Some granules (1) are unreactive while others (2) are intensely stained by tannic acid–osmium. Other granules (3) are swollen and their contents diluted. A channel of the OCS connects the third (3) organelle to the surface on the other side of the platelet. A dilated connection of the OCS to the surface is evident on the right side of this cell (fixation: Glut-TA-OsA). Magnification × 25,000. Fig. 6. Platelet from washed suspension exposed to thrombin at a concentration of 5 U/mL for one minute in the presence of EDTA. A channel of the OCS filled with granule contents follows a tortuous course from one side of the centrally concentrated contractile gel (CG) and constricted ring of microtubules (MT) to an opening on the opposite side. Tannic acid–osmium stained material appears to have been fixed in the process of extrusion from the opening (fixation: Glut-TA-OsA). Magnification × 29,000.











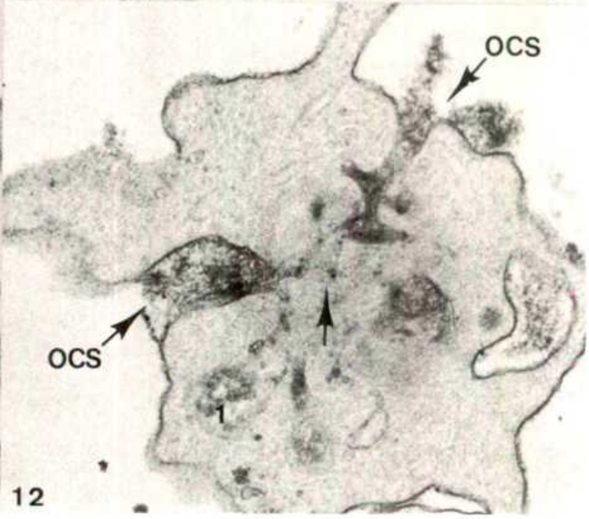


Fig 7. Platelet from EDTA washed suspension combined with thrombin at 1 U/mL for five minutes. A tortuous channel filled with tannic acid–osmium stained material passes from one side of the platelet to the other and opens on the surface. Granules (G) are connected to the channel which has dilated and narrow (↑) segments (fixation: Glut-TA-OsA). Magnification × 29,000. Fig 8. EDTA washed platelet exposed to 3 U/mL of thrombin for five minutes. Stained (1) and swollen (2) granules are directly connected to the channel filled with material reacting with tannic acid–osmium. Other swollen granules, such as (3), are connected to different channels of the OCS and pass out of the plane of section. Microtubules (MT) are constricted into the central mass of contractile gel (fixation: Glut-TA-OsA). Magnification × 29,000. Fig 9. Platelet from washed suspension containing EDTA and exposed to thrombin (3 U/mL) for three minutes. A complex channel of the OCS is imbedded in the central mass of contractile gel (CG). The channels are an interconnected spiderweb of

and caused intense staining by osmic acid. The observation prompted the studies carried out in this investigation. Tannic acid, when combined with PPP or solutions of purified fibrinogen in the same manner used during glutaraldehyde fixation, caused immediate formation of precipitates. The amorphous and fibrillar material present in the precipitates resembled the fibrinogen and fibrin in tannic acid–stained, fixed samples of resting or activated C-PRP. Addition of thrombin to plasma or fibrinogen solutions before tannic acid resulted in selective deposition of osmic acid on fibrin strands.

The present investigation has used this feature of tannic acid pharmacology to evaluate the release reaction in thrombin-aggregated and -activated platelets. Fibrinogen is a major constituent of platelet alpha granules and is extruded from activated platelets during release.[48] It seemed possible that tannic acid might combine with fibrinogen and selectively deposit osmic acid during transfer of the clottable protein from cytoplasmic organelles to the platelet exterior. Thrombin-aggregated platelets in PRP samples stained with tannic acid were identical to control aggregates, except for the osmium staining reaction. The amorphous, dense precipitate surrounding aggregates and concentrated in spaces between cells resembled the precipitate formed in solutions of fibrinogen after addition of tannic acid. A similar electron-dense material was evident in some of the platelet alpha granules and filling narrow and dilated elements of the OCS. Although alpha granules did not react with tannic acid in resting platelets, many normal-sized and swollen granules in aggregated cells were intensely stained by tannic acid–osmium. Filamentous material and strands filling dilated channels and swollen granules were identical in appearance to electron-dense fibers in thrombin-clotted fibrinogen solutions.

Involvement of granules and channels in the platelet secretory process was clearly shown in the study of individual cells. Washed platelets exposed to thrombin in the presence of EDTA did not reveal the amorphous electron-dense precipitate outside the cells as seen in thrombin-aggregated C-PRP because nearly all of the fibrinogen was removed during preparation and resuspension. The internal platelet changes, however, were essentially identical. Thrombin stimulation caused shape change, central movement of organelles, and constriction of microtubule coils and microfilaments into a contractile gel. Whereas granules and lumina of OCS channels were unstained in resting platelets fixed in the presence of tannic acid, osmium-reactive material filled the dilated OCS of thrombin-activated platelets and stained granules attached to the channels intensely. Other granules and organelles not in continuity with the OCS remained unstained. The appearance suggested that tannic acid reaches the interior of granules by traversing channels of the OCS, rather than by diffusing through cell membranes and cytoplasm.[44] The reaction to thrombin breaches the membrane barrier between channels and granules so that they are in direct continuity. Many proteins are secreted from platelet alpha granules,[48] and tannic acid, as used in this study, may combine with them. Yet, our studies show that tannic acid reacts with fibrinogen and fibrin, and selectively deposits osmium. As a result, it is reasonable to suggest that tannic acid identifies the secretion of fibrinogen from granules to channels, and through connections with the cell surface to the exterior of thrombin-activated platelets.

Evidence favoring an alternative secretory pathway involving fusion of centrally concentrated granules to each other, formation of a closed vacuole filled with substances from the organelles, migration to the surface, attachment to the cell wall, and discharge of contents to the outside[12,13] was not encountered in the present study. The possibility that centrally concentrated granules might fuse with each other at an early stage in the secretory process has been attractive for many years and was suggested in early investigations.[49] That granules can fuse with each other has been demonstrated in studies of platelets from individuals with inherited and acquired platelet disorders.[50-52] More concrete evidence has been provided by investigations of platelet morphology during long-term storage in vitro.[53] Fusion of normal-sized organelles to form giant granules is a common finding after storage under mildly alkaline conditions for seven to 21 days. A stage of fusion similar to that observed in long-term–stored platelets would seem essential in formation of closed secretion vacuoles. Although the appearance of vacuoles in thrombin-activated platelets has frequently been reported,[10,14] none of the studies has shown that fusion of granules into a membrane-enclosed mass precedes development of empty sacs. Apparent fusion of two granules was reported in a previous study of platelet secretion employing tannic acid.[54] In our experience, however, such an event is extremely rare.

A possible explanation for development of vacuoles in thrombin-treated platelets is provided by the present study. After establishing communication with channels of the OCS, granules become swollen. Often several granules are attached to a single channel. Dilatation of the channel and

canaliculi. Segments of cytoplasm (C) often appear isolated by the interconnected canaliculi, which dilate as they fill with granule contents. Electron-dense material appears to be in the process of extrusion from this cell (fixation: Glut-TA-OsA). Magnification × 29,000. Fig 10. Platelet from sample of EDTA washed platelets exposed to thrombin at 3 U/mL for one minute. Electron-dense material is in the process of extrusion from four different sites (↑) on the surface of this cell. One of the channels inside the cell communicates with two different openings of the OCS and with a granule (1). Other granules (2) are not stained by tannic acid–osmium (fixation: Glut-TA-OsA). Magnification × 29,000. Fig 11. EDTA washed platelets combined with 5 U/mL of thrombin for five minutes. A third example showing a channel of the OCS opening at two different sites on the platelet surface. They demonstrate clearly that granules do not form closed sacs that migrate to and fuse with the cell surface. Transplatelet channels communicating with opposite surfaces of the same cell are inconsistent with that concept (fixation: Glut-TA-OsA). Magnification × 29,000. Fig 12. EDTA washed platelets following exposure to thrombin at 3 U/mL for three minutes. Another example in which a channel stretches from one side of the platelet to the other side and opens at two separate sites on the cell surface. One granule (1) connects directly to the transplatelet channel. The central portion of the canaliculus (↑) is less intensely stained, but can easily be identified (fixation: Glut-TA-OsA). Magnification × 29,000.

attached granules would and does yield the appearance of a large vacuole. The channels often appear dilated in the cytoplasm, but narrow at the cell surface.[54,55] Swelling of granules and channels with persistent narrowing of the OCS opening would produce the appearance of a distended vacuole close to the cell wall when viewed in a fluorescence microscope after staining with a monoclonal antibody to a specific granule constituent.[12,13]

In conclusion, the present study has reexamined involvement of the surface-connected, open-canalicular system in secretion by human platelets stained with tannic acid following exposure to thrombin in the presence or absence of EDTA. Findings of the investigation confirm earlier studies which suggested that channels of the OCS were major conduits for discharge of products secreted during the human platelet release reaction. Granules are concentrated in centers of thrombin-activated platelets, but fusion of the organelles to each other resulting in formation of closed sacs was not observed. Instead the sequence of granule interaction with channels, establishment of continuity, swelling of channels and granules as secretory products are exposed to the medium, and discharge through narrow and dilated openings of OCS on platelet surfaces was clearly demonstrated by fixation in the presence of tannic acid. Efforts to apply this procedure to platelets from a patient with congenital afribrinogenemia are currently in progress.

The Syndrome of T8 Hyperlymphocytosis: Variation in Phenotype and Cytotoxic Activities of Granular Cells and Evaluation of Their Role in Associated Neutropenia

By Catherine Grillot-Courvalin, Giovanna Vinci, Andreas Tsapis, Marie-Christine Dokhelar,
William Vainchenker, and Jean-Claude Brouet

We performed a longitudinal study of the phenotype and functions of granular lymphoid cells from seven patients with T_8 hyperlymphocytosis and neutropenia. Whereas cells retained a T3+ T8+ (six cases) or T3− T8+ (one case) phenotype at different examinations, the expression of natural killer (NK)-related antigens (HNK1- and Leu11-defined antigens) exhibited striking variations, some of which were also observed after in vitro culture. Similarly, natural or antibody-mediated cytotoxic activities fluctuated in vivo and in vitro. Cells from the patient with T3− T8+ proliferation were able to inhibit directly the growth of early CFU-GM, CFU-E, and BFU-E and to a lesser extent of late CFU-GM, as shown by cultures of autologous blood or marrow progenitors after depletion (and subsequent addition) of granular cells. In the other six patients with T3+ T8+ cells, no such effect was found. However, after a 24-hour incubation of the progenitors with the granular cells, CFU-GM growth was clearly inhibited; this was not observed in all experiments, a finding which may be related to the spontaneous variations of cell killer functions. Finally, no correlation was noted between the clinical course or extent of lymphoid proliferation and cell function or phenotype or with the monoclonal (two cases), polyclonal (three cases) or germ-line (one case) patterns of T cell receptor β gene configuration.

© 1987 by Grune & Stratton, Inc.

RECENTLY, THE ASSOCIATION of chronic T8 hyperlymphocytosis and neutropenia has been the subject of several reports, since it represents a distinct new clinical, morphological, and immunological disorder, the pathogenesis of which is still largely unknown.[1-4] Because of their strong similarity to large granular lymphocytes (LGL) and the occurrence of cytopenia, T8 cells from these patients have been studied mainly for killer and suppressive activities, with contradictory results. These cells frequently display antibody-dependent cell cytotoxicity (ADCC),[3,5-7] whereas evaluation of natural killer (NK) activity or suppression on Ig synthesis or hemopoietic cell maturation yielded opposite results in different studies.[3,6-15]

We report here striking variations of the cell surface phenotype and/or functions in a longitudinal study of seven patients with T8 hyperlymphocytosis and neutropenia. Some of these modifications also occurred after short term in vitro cell cultures. These unexpected variations may be germane to the above-mentioned discrepancies and to the difficulty encountered in understanding the physiopathology of this disorder. Studies in six cases of T cell receptor β chain gene organization showed unrearranged, polyclonal, or monoclonal patterns without clear-cut correlations with clinical data or course of the disease.

MATERIALS AND METHODS

Patients. Seven patients with T8 hyperlymphocytosis and neutropenia were studied. The main clinical and hematologic data are listed in Table 1. Their clinical condition remained stable during a two- to 18-year follow-up period. There were no life-threatening infections in any patient, although recurrent upper respiratory infections occurred in five patients. In all cases, the majority of blood lymphoid cells were medium- or large-sized granular cells with azurophilic granules and strong acid phosphatase positivity. Peripheral thrombocytopenia as assessed by a reduced half-life of autologous ^{51}Cr-labeled platelets (two and three days for patients 6 and 4, respectively) was observed in two patients. Ferrokinetic studies were performed in the two anemic patients. In patient 1, there was a mild autoimmune Coombs test–negative hemolysis with a splenic sequestration. In patient 5, there were both a low production and abnormal maturation of red cells.

A definite bone marrow lymphoid infiltration was observed in four patients at biopsy; the granulocytic series appeared normal or slightly hypoplastic. Monoclonal Ig were detected in two patients: patient 1 had a γ 3 heavy chain disease protein with bone marrow and spleen plasmacytic infiltration; a monoclonal IgG lambda was found in serum of patient 3. No Ig abnormalities were observed in the other patients.

Cell isolation and phenotype. Mononuclear cells were isolated from peripheral heparinized blood or bone marrow by centrifugation on Ficoll Hypaque density gradients. In patient 1, spleen cells were obtained by gentle teasing of the organ. In some experiments, E-rosetting cells were isolated and rosetting lymphocytes recovered after hypotonic lysis of sheep red cells; in some preparations, T8 cells were eliminated by complement-dependent cytotoxicity.

The cells were studied with a panel of monoclonal antibodies (Mab) by indirect fluorescence using fluoresceinated goat IgG to mouse Ig as a second layer. Anti-T cell Mab were directed against T3, T4, T8, T6, and Tac (IL2 receptor) antigens. Mab directed to LGL included HNK1 (Leu 7), Leu 11, NKH1, and NKH2.[16] K5 Mab directed to class II DR antigens was produced in our laboratory. B cell surface Ig were detected by direct fluorescence with monospecific, rhodamine-conjugated Fab'2 fragments of rabbit IgG to human heavy and light Ig chains. Cell surface phenotype was determined on fresh cells and in certain cases after three days in vitro culture in RPMI 10% fetal calf serum (FCS) medium with or without addition of 10% T cell–conditioned medium (a supernatant of T cells stimulated for 48 hours with phytohemagglutinin).

get cells used for NK assay were the erythroleukemic K562 cells and for ADCC L1210 leukemic cells sensitized by rabbit anti-L1210 antibodies. ^{51}Chromium-labeled cells and patient cells were incubated in triplicate at various effector/target ratios in microtiter plates for four hours at 37°C and 100 μL of cell free supernatants were collected and counted for ^{51}Cr release in a γ counter. The percentage cytotoxicity was calculated as follows: % cytotoxicity: (experimental release – spontaneous release) × 100/maximum release – spontaneous release.

Clonogenic assays. Marrow or peripheral blood mononuclear cells were obtained after informed consent; they were cultured, usually in triplicate, using the plasma clot technique.[17] The final medium consisted of alpha medium (Eurobio, Paris) 10% human AB serum, 1% deionized bovine serum albumin, 70 μg/mL $CaCl_2$ and 10% bovine citrated plasma. Several stimulating factors for CFU-GM growth were used, ie, Mo-,[18] 5637-,[19] and GCT[20]-conditioned media and phytohemagglutinin leukocyte conditioned medium. In some experiments, erythroid colonies were grown by adding 1 U/mL porcine erythropoietin (CNTS, Paris), to 5% Mo-conditioned medium. At day 12 to 14 CFU-GM- or BFU-E-derived colonies were enumerated under an inverted microscope; CFU-E colonies were counted at day 7.

Blood mononuclear cells depleted of T cells were plated at 5 × 10^4 to 2 × 10^5 cells/mL. Purified E-rosetting T cells were added at different concentrations (1 × 10^5 to 1 × 10^6/mL) to the non-T cells obtained from the patient or normal individuals. In other experiments, blood or marrow mononuclear cells depleted of T cells, T cells alone, or a mixture of mononuclear cells depleted of T cells and T cells in a 1/4 ratio, were incubated overnight at 5 × 10^5/mL in alpha medium 10% FCS at 37°C. Cells were then centrifuged and counted. Individual populations of cells or mixed populations were assayed for colony formation. In some experiments sera of the patients were added at 10% final concentration.

Analysis of T cell receptor beta chain genes. High-molecular weight DNA was extracted from blood mononuclear cells and from patient 1 spleen T8 cells. DNA was digested with the restriction enzymes *Bam*HI, *Eco*RI, and *Hind*III and fractionated on 0.8% agarose gels. DNA fragments were transferred by the Southern process to nitrocellulose paper. Hybridization with ^{32}P-labeled probe for the C β constant gene of T cell receptor (400bp *Bgl*I-*Bgl*I fragment containing human C β gene sequence) was performed, followed by washing at the appropriate stringency (0.1 × SSC, 0.2% SDS, 65°C) and radioautography.

RESULTS

Cell phenotype. The majority of T cells from six patients formed E-rosettes and expressed both T3 and T8 antigens (Table 2); the density of T8 antigen often appeared quite low by eye fluorescence in comparison to that of normal blood cells; however, this phenotype remained stable at different examinations and after in vitro culture in RPMI FCS medium. The majority of these T3+ T8+ cells did not express class II antigens. The cells of patient 7 formed E-rosettes but expressed only T8 antigen. Four different markers of LGL were studied; the expression of HNK1 antigen was constant, although the percentage of positive cells changed strikingly in the same patient at different times (Table 2) or after three days of in vitro culture in patient 2. Cells from only five patients were stained with Leu 11 Mab, which reacts with a Fc receptor-related epitope; again, large variations in the percentage of positive cells were noted in patients 4 and 6 in different experiments; Leu 11 expression was lost after in vitro culture in all cases studied (Table 2). Neither before nor after in vitro culture did the cells express two other NK cell-related antigens, identified by NKH1 and NKH2 Mab, which react with the majority or a subset of blood LGL, respectively. Mab directed to IL2 receptor (Tac) strongly stained 10% of T3+ T8+ cells in the spleen of patient 1 and 2% of blood cells in patient 3, whereas it was negative on peripheral blood leukocytes (PBL) from the other patients.

Killer function. Since the above results showed variations in cell phenotype at different times, we performed a longitudinal study of ADCC and NK activity in 6 patients.

PBL from patients 2 and 5 displayed a normal ADCC function in the single assay performed. Cells from patient 1 exhibited similar ADCC levels (50% Cr release as compared to normal PBL) on two separate tests. Divergent results were observed in patient 3, who was studied twice at six-month intervals (normal *v* absent ADCC).

NK function of freshly drawn PBL was studied during a 2-year period (Table 3). In patients 1, 4, and 5, NK activity was abnormally low or absent. Discordant results (normal *v* low activity) were obtained in patients 2, 3, and 6 in separate examinations. NK activity of spleen cells from patient 1 was studied; unseparated cells, purified T cells, and T4-depleted T cells exhibited a similar killer function, ascertaining therefore that the T8 subset mediated this effect. Unexpectedly, a fair NK activity was recovered after 48-to 72-hour in vitro culture in RPMI-FCS medium in all patients tested (Table 3). This activity was slightly enhanced when cells were

cultivated in phytohemagglutinin-conditioned medium (data not shown). These modifications were not related to an expansion of residual NK cells with a full phenotype of LGL, since phenotyping of the cultured cells did not disclose a sizable number of NKH1- or NKH2-reactive cells.

Clonogenic assays. In the first six patients, CFU-GM from blood cells were normal or quite high in patients 5 and 6 and markedly diminished in the others. Assays were repeated two to four times during a 2-year period and no marked difference in the plating efficiency was observed. Similar results were obtained whatever the stimulating factor used. The effect of T cell depletion by E-rosetting and of their subsequent addition was studied in all patients (Table 4). Depletion of T cells did not enhance colony formation and accordingly their addition did not decrease the number of colonies but even led to enhancement of colony formation in some experiments. Addition of T cells even at a very high concentration (up to 1 × 10^6 cells/mL) had no inhibitory effects. Results using marrow cells were identical (Table 5). In order to exclude that after E-rosetting, a small amount of remaining T3+ T8+ cells could still inhibit CFU-GM colony formation in patients with a low plating efficiency, T8 complement-mediated cytotoxicity was performed on T-depleted blood mononuclear cells from patients 2 and 4 and on T-depleted marrow cells from patient 2. Colony formation was not enhanced and addition of T cells did not alter the growth of progenitors. T cells from all patients were cultured with allogeneic normal marrow cells; no inhibition of colony formation was observed (data not shown).

When T cells were incubated for 24 to 48 hours in liquid medium and then added back to T-depleted mononuclear cells, no inhibition of colony growth in three patients was observed. In contrast, in patients 2, 5 and 6, a marked inhibition of CFU-GM colony formation was observed when T cells and T-depleted blood or marrow mononuclear cells were incubated together and then plated in semisolid medium (Table 6). This result was obtained both when using blood or marrow cells as the target for patient 2. However, this result was not observed in all experiments; a marked inhibition was detected in three of five different occasions during an 18-month period for patient 2, and once in two experiments for patients 5 and 6. Sera from all patients were tested in culture (and in preincubation experiments in three patients); no inhibition of colony formation was noted. Studies of CFU-E colonies were performed in patient 5, who was anemic. T cell–depleted cultures yielded a normal number of colonies (260 colonies/10^5 cells); addition of PBL T cells clearly suppressed CFU-E growth (32% inhibition, $0.05 < p < 0.01$).

Similar experiments were performed in patient 7 whose cells had a T3− T8+ phenotype. Studies of blood cell progenitors (Table 4) showed that depletion of T cells by E-rosetting allowed the growth of CFU-GM, whereas their subsequent addition inhibited colony growth. However, no

clear effect was observed on marrow CFU-GM–derived colonies (Table 5). In addition E+ cells were able to significantly inhibit marrow CFU-E and BFU-E growth ($p < 0.01$); however, they still had no definite effect on marrow CFU-GM growth. When E+ cells from this patient were incubated for 24 to 48 hours with T-depleted marrow or blood cells, inhibition of blood CFU-GM, CFU-E, and BFU-E colony formation was again observed, but no significant effect on marrow CFU-GM colony formation could be recorded.

7	0	23 ± 2	3 ± 1

T cells were depleted by E-rosetting. E$^-$ and E$^+$ were recovered and counted. E$^-$ were seeded at a concentration equivalent to their presence in 1 × 10^6 nonseparated mononuclear cells. The number of E$^-$ was usually 1 × 10^5 cells/mL. E$^+$ were added at a different concentration which did not change the plating efficiency. Results reflect the addition of E$^+$ in 1/9 ratio.

Table 5. CFU-GM Colony Formation From Marrow Cells (Day 7)

Patient	Mononuclear Cells (10^5 Cells/mL)	T-Depleted Cells	E$^-$ and T Cells at a ⅑ Ratio
1	50 ± 10	25 ± 4	53 ± 8
2	96 ± 20	90 ± 15	93 ± 18
5	ND	485 ± 32	494 ± 8
7	ND	200 ± 14	196 ± 14

Experiments were performed as detailed in Table 4, except that colonies were enumerated at day 7.

ND, not determined.

Analysis of T cell receptor beta chain gene organization. DNA from all cases except patient 2 was studied for T cell receptor beta chain gene configuration. In patients 5 and 6, a monoclonal rearrangement was observed after digestion of DNA with *Bam*HI and *Hind*III; with *Eco*RI the 11-Kb band had a markedly decreased intensity, but a rearranged band was detectable only in patient 5 (Fig 1). In patient 7, beta chain genes were in germ-line configuration. In the three remaining patients, no rearranged band was detected after DNA digestion with the three enzymes (Fig 1). A decrease of the intensity of germ-line bands in these cases is indicative of polyclonal T cell population.

DISCUSSION

The seven patients studied were affected with the recently characterized syndrome of T8 hyperlymphocytosis with neutropenia. Their disease followed a chronic course characterized by hyperlymphocytosis (which spared bone marrow in three cases), neutropenia, and frequent, mild infections.

Two patients had monoclonal Ig, a hitherto-unreported finding in such patients. Patient 1 had a $\gamma 3$ heavy chain disease protein with plasmacytic infiltration of spleen and bone marrow, and patient 3 a $\gamma\lambda$ monoclonal Ig that was detected after three-year follow-up and remained stable thereafter. Although such Ig abnormalities appear distinctly unusual, the occurrence of polyclonal hypergammaglobulinemia as well as various autoantibodies are frequent in this syndrome.[3,13,14] Whether these abnormalities are somehow related to the T cell disorder is presently unknown.

In all patients, the cells had the morphology of medium-sized or large lymphocytes with azurophilic granules. In one

DNA was digested with *Bam*HI (A), *Eco*RI (B) and *Hind*III (C) restriction enzymes. Horizontal bars indicate germ line fragments; arrows, rearranged fragments.

case (patient 7) cells were devoid of T3 antigens, possessed germ-line T cell receptor beta chain genes and expressed some NK cell–related markers (HNK1 and Leu 11, reactivity) as well as T8 antigen. In the other six cases, they belonged unequivocally to the T cell series as shown by the expression of T3 and T8 antigens and by the configuration of T cell receptor beta chain genes. They also possessed some of the known markers of LGL, namely HNK1 (seven cases) and Leu 11 (five cases). However, only a percentage of T3+ and T8+ cells bore these antigens and longitudinal studies showed striking variations of the subset of cells expressing detectable levels of these NK-related antigens; some of these variations could be observed after in vitro culture. These modifications contrasted with the stable T3+ T8+ phenotype of the majority of PBL of blood cells and do not support the suggestion that there is significant heterogeneity within the expanded lymphocytic population.[8] Moreover, in patient 1, the percentage of HNK1 reactivity among the T3+ T8+ cells was different in the blood or spleen. The constant absence of NKH1 and NKH2 markers which identify the majority of functional NK cells (or subsets) argues against the possibility that the observed variations are related to a T3− normal residual LGL population; it indicates furthermore that the T3+ T8+ HNK1+ cells characteristic of this syndrome belong to a distinct population of NK cells. This finding therefore reinforces the rationale to characterize the syndrome of T8 hyperlymphocytosis with neutropenia.

More importantly, this longitudinal study also revealed variations in both natural and antibody-dependent killer activities. The significance of these phenotypic and functional fluctuations remains uncertain; interestingly, they were also recorded in primary and transplanted tumors of the rat LGL leukemia.[21] NK function was restored after in vitro culture but we could not find any serum inhibitor, as suggested for normal LGL[22] and in another case of T8 hyperlymphocytosis.[23] Anyway, our data are probably germane to the discordant results previously published.

The benign or malignant nature of this syndrome is still controversial. Cytogenetic studies as well as the clinical course[13,14,24-26] undoubtedly suggest that at least some patients have an indeed malignant disease; no clinical or immunological data, however, delineate this subset of patients. Investigation of clonal rearrangements of T cell receptor β chain genes of the expanded population of granular lymphocytes does not resolve this issue. In our patients with T3+ T8+ phenotype a clonal rearrangement was observed in two cases, while a polyclonal pattern was noted in three other patients as shown by a decreased intensity of germ-line bands and the absence of rearranged DNA fragments. In the patient with T3− T8+ cells, T cell receptor genes appeared in the germ-line configuration. Similar studies have been performed in 23 other patients with T8 hyperlymphocytosis and neutropenia[27-30]; clonal rearrangements were noted in 17 cases and polyclonal or germ-line pattern in the other cases. In one large study, only T3− T8+ cells had germ line pattern whereas all T3+ T8+ cells appeared monoclonal.[29] The absence of detailed cell phenotypes in the other reported cases with unrearranged pattern precludes definite conclusions about the incidence of polyclonal T3+ T8+ hyperlymphocytosis. It should be stressed that in our series no clinical, hematological, or immunological features, neither duration of the disease nor bone marrow or spleen lymphoid involvement, distinguish our patients with clonal disorder. The rather uniform clinical and immunological data (and especially the discrete NK-related phenotype as outlined above) may suggest a polyclonal expansion of a subset of NK-related cells, driven by an unknown event or secondary to the neutropenia, with the possibility of a late clonal evolution. The derivation of NK cells is still debatable. From the above data it can be hypothesized either that the two phenotypes (T3− T8+ and T3+ T8+) correspond to different lineages, or that T3− T8+ cells with high NK activity represent precursors of T cell lineage.

It should be noted that the existence of polyclonal T3+

T8+ cells as well as that of T3− T8+ hyperlymphocytosis does not support the possibility that the neutropenia is due to an interaction involving the conventional T cell receptor. Indeed the role of granular lymphoid cells in the genesis of cytopenia in these patients is still uncertain. In previous reports, a consistent inhibition of colony-forming cells has been noted only for erythroid progenitors in patients with anemia.[3,12] In contrast, most studies failed to demonstrate any effect of expanded granular cells on granulopoiesis, even when the cells had some suppressive properties on cell proliferation or Ig synthesis by B cells in vitro.[1,3,6,14]

We reevaluated here the possible interaction of T8+ cells with myeloid progenitors using a number of assays. Two different situations could be distinguished. First, cells from patient 7 with T3− T8+ phenotype directly interfered with hemopoietic progenitors; depletion of T8+ cells led to a striking increase of both early CFU-GM and BFU-E; likewise, addition of the purified granular cells inhibited early CFU-GM, CFU-E, and BFU-E but had no effect on late CFU-GM colonies. This activity is reminiscent of that exerted by normal LGL,[31-34] although studies of inhibitory effects of LGL on hematopoietic cells led to some discrepancies, possibly because of technical conditions. Like normal LGL, granular cells from this patient had unrearranged T cell receptor β chain genes; whether their effect is mediated by direct contact or production of colony inhibiting factor as shown for normal LGL[32] remains to be established.

Studies performed in the six other patients with T3+ T8+ cells were in sharp contrast with the latter results. No modification of colony growth was observed after depletion (and subsequent addition) of granular T3+ T8+ cells in 18 experiments performed in the six patients. These patients had either a normal colony growth (two cases) or a reduced one (four cases), a reproducible finding at different examinations. Therefore, we obtained no evidence that cells directly suppress hemopoiesis. These cells are obviously different from the suppressive T cell population, which has been shown to inhibit with a class II restriction hemopoiesis in normal subjects[35-37] or in disease states,[36,37] and which feature a T8+ HNK1+ T3+ DR+ phenotype.

Cultures in autologous serum yielded similar results, making unlikely a role for antineutrophil antibodies that were present in the serum of four patients as noted in some reports[5,14] but not others.[3,6] However, a role for ADCC is not ruled out by our experiments if sensitized progenitors are unavailable to study because of in vitro destruction.

We next explored the possibility that T3+ T8+ cells from these patients need to interact with progenitors or some kind of activation to become suppressive. Indeed, the finding in patient 1 of T3+ T8+ cells expressing IL 2 receptors in spleen but not blood may indicate that suppressive cells do not circulate and may be locally activated. In fact, preincubation of T cells with blood or marrow progenitors led to significant inhibition in three of six patients. However, this inhibition was not observed in all experiments (three of five assays in patient 2 and one of two in patients 5 and 6). Such variations could well be related to the changes occurring in phenotype and function of T8 cells as demonstrated in this report. Interestingly, such preincubation is considered necessary for normal LGL cells to act on hemopoiesis in some reports.[31,32]

Finally, although we cannot exclude the possibility that T cells do not play a major role in neutropenia in these patients, it is worth noting that patients 1 and 5 recovered a normal WBC and differential count after a 6-month chemotherapeutic regimen (intermittent prednisone, vincristine, and cyclophosphamide) given for associated lymphoid malignancy and marked anemia, respectively. Likewise, there was a clearing of the expanded T3+ T8+ cell population with normal ratio of T4/T8 cells.

ACKNOWLEDGMENT

We thank Dr T. Hercend, C. Mawas and T.A. Waldmann for their kind gift of monoclonal reagents and P. Strominger who provided the T cell β chain probe.

Role of Colony-Stimulating Factor in Myelopoiesis in Murine Long-Term Bone Marrow Cultures

By D.A. Lipschitz, K.B. Udupa, J.M. Taylor, R.K. Shadduck, and A. Waheed

Weekly medium change or midweek feeding of long-term bone marrow cultures (LTMBCs) results in a significant increase in total myeloid cell production. Proliferative myeloid cells peak 48 hours after feeding, and nonproliferative myeloid cells reach maximum levels at 72 hours. This increase in myelopoiesis is invariably preceded by a significant elevation in biologically and immunologically measurable colony-stimulating factor (CSF) in the supernatants of LTBMC. The level peaks 24 hours after medium change, then gradually returns to basal values. The decrease in CSF relates to its consumption by generating myeloid precursors because no fluctuation in the levels occur in cultures without active myelopoiesis. No significant inhibitors or promoters of CSF were detected. When highly purified L cell CSF, CSF in lung-conditioned medium, or CSF concentrated from LTBMC supernatant is added to cultures, an identical increase in myelopoiesis occurs. Anti-CSF antiserum, added to culture at the time of medium change, totally neutralizes supernatant CSF levels but does not affect myelopoiesis. These findings suggest a potential regulatory role for CSF in myelopoiesis in LTBMC. CSF appears to function within the microenvironment through a mechanism involving cell:cell interactions or by causing the production of other substances that stimulate myelopoiesis. Because exogenous CSF stimulates myelopoiesis, it is likely that it too can react either directly or through microenvironmental cells to stimulate primitive myeloid cells to divide.

© 1987 by Grune & Stratton, Inc.

RECENTLY tissue culture techniques have been developed that permit long-term maintenance of bone marrow cells in vitro for up to 50 weeks.[1-3] The key component of the culture system is the formation of an adherent microenvironmental layer that allows proliferation and differentiation of hematopoietic stem cells into predominantly mature myeloid precursors. These myeloid cells become nonadherent and can be harvested at weekly intervals from the culture medium. The cellular and morphological characteristics of hematopoiesis in long-term bone marrow culture (LTBMC) bear many similarities to normal hematopoietic function in vivo. This culture system has been extensively used to determine the role of colony-stimulating factor (CSF) in the regulation of myelopoiesis. Early work failed to detect measurable CSF in culture, and other studies demonstrated no increase in myelopoiesis when CSF from different sources was added to culture. These included CSF contained in lung-conditioned medium (LCM), WEHI-3 cell-conditioned medium, and L cell CSF condition medium.[4,5] Furthermore, addition of anti-CSF antiserum had no apparent effect on myeloid cell production. This led to the suggestion that myelopoiesis in LTBMC was independent of CSF or alternatively, that CSF production was minimal and functioned exclusively locally. More recent studies provided stronger evidence indicating a direct regulatory role of CSF in myelopoiesis in LTBMC. Using a bilayer agar culture system, Heard and colleagues were easily able to detect significant amounts of CSF production in LTBMCs.[6] A relationship between myeloid cell production and CSF levels was suggested by the very high levels of CSF found in hematopoietically inactive cultures and a marked decrease in its level when these adherent layers were recharged. Furthermore, an inverse correlation between supernatant cell recovery prior to the assay and the level of CSF was noted. Gualtieri and co-workers provided further support for the importance of CSF in myelopoiesis in LTBMC.[7] Using a method similar to that described by Heard and colleagues, they demonstrated a dose-dependent increase in CSF when LTBMCs were exposed to ionizing irradiation. The CSF increase correlated inversely with the reduction in myelopoiesis induced by irradiation.

Recently, we developed a micromethod of LTBMC that allows initiation of numerous individual cultures from a single donor animal and makes possible frequent assessment of culture characteristics.[8] Using this method, we showed that a predictable increase in myelopoiesis occurs following weekly medium change. In this study, we examined the kinetics of day-to-day variations in myeloid cell production in vitro and the potential role of CSF in these events.

MATERIALS AND METHODS

Long-term bone marrow cultures were studied using a micromethod reported recently.[8] This is a modification of the method developed initially by Dexter and colleagues[1] and subsequently modified by Mauch and co-workers.[2] Marrow from the femora and tibia of 3-month-old C57BL/6 mice were flushed into α-medium (Flow Laboratories, McClean, VA) with a 1-mL syringe fitted with a 23-gauge needle. The cells were aspirated repeatedly to form a single cell suspension. After determination of the cell count with a model ZF Coulter counter (Coulter Electronics, Hialeah, FL), 1.4×10^6 cells were added to Linbro wells (Flow Laboratories) in a medium containing 65% α-medium, 25% horse serum, and 10^{-5} mol/L of hydrocortisone (10%) to a final volume of 0.7 mL. In some

studies, cultures were set up identically except that hydrocortisone was omitted. The Linbro wells were placed in sterile covered Petri dishes and incubated in a water-jacketed incubator at 33°C in a humidified atmosphere with 5% CO_2. At weekly intervals, half the supernatant was removed from each well and replaced with an equal volume of fresh medium that was identical to that removed.

Colony-stimulating factor was measured serially in the culture supernatant starting 4 weeks after initiation of the cultures. In addition, the total number of cells in the culture and the fraction of the total that were either adherent layer cells or myeloid cells were determined. The culture supernatant was removed gently and centrifuged at 250 g for 10 minutes at 4°C and used for measurement of CSF as described below. α-Medium (0.5 mL) was added to the LTBMCs, and the adherent layers were freed using a rubber policeman. A single cell suspension was made by passage back and forth three times through a 23-gauge needle. These cells were mixed with those recovered from the supernatant and made up to a 1-mL vol. The cell count was determined in a Coulter counter and recorded as total cells per well. A cytospin preparation made from each cell suspension was stained with Wright's Giemsa, and a 200-cell differential count was performed on each. Cells were categorized as proliferative (myeloblast, promyelocyte, myelocyte) and nonproliferative (metamyelocyte, band, and polymorphonuclear neutrophil) myeloid cells and others (which included stromal cells).

Biologically active CSF was measured by assessing colony number when 1×10^5 fresh murine bone marrow cells were cultured for CFU-C in the presence of 10% supernatant from LTBMCs. The method used was that described by Worton and colleagues.[9] Medium consisted of 0.8% methylcellulose, 30% fetal bovine serum (FBS) (Flow Laboratories) and 1% bovine serum albumin (BSA) (Sigma, St Louis). The culture was added to a 35-mm dish and incubated for seven days in a water-jacketed incubator at 37°C in an atmosphere 5% CO_2. As a positive control, CFU-C were measured using LCM as the source of CSF.[10] The concentration of LCM used was that which caused maximal stimulation of colony formation. Additional cultures used, as a negative control, fresh medium used to refeed LTBMC. Three CFU-C cultures were set up for the assay of each sample. With an inverted microscope, colonies of $\geq$50 cells were counted on day 7 after the culture was initiated. Immunoreactive CSF was measured by a double-antibody radioimmunoassay (RIA).[11,12]

In some studies, the effect of adding small volumes of LCM, a tenfold concentrate of LTBMC supernatant obtained 24 hours after refeeding, or purified L cell CSF on myeloid cell production was examined. The L cell CSF was produced by culture of murine L cells in serum-free CMRL 1066 medium. A 10-L pool of conditioned medium was concentrated 250-fold by ultrafiltration using an Amicon PM 10 membrane. This material was applied to an affinity column to which purified anti-CSF was bound covalently. After being washed with buffer, the purified CSF was eluted with 2 mol/L of guanidine, pH 4.0[13] The final material appeared homogenous in sodium dodecyl sulfate (SDS)-acrylamide gel and had a specific activity of 7.5×10^7 U/mg of protein.

Antibodies to CSF were produced in a New Zealand white rabbit by multiple intradermal injections of 20 µg of purified CSF emulsified in Freund's complete adjuvant.[13-15] The antiserum used in these studies had a 50% neutralization titer of 1:2048 as judged by assay against an L cell CSF standard.

RESULTS

In a first series of experiments, LTBMC cell number, myeloid cells, and CSF from week-4 cultures were measured for 7 consecutive days beginning at the time of refeeding. Each day, six culture wells were examined; the results represent the mean (± SEM) of seven experiments conducted over 1 week (Fig 1). Refeeding of the culture increased the total cell number significantly three days later ($P < .001$), returning to the premedium change value by day 7. This cell increase was due exclusively to increases in the number of myeloid cells. Proliferative myeloid cells reached a peak two days after feeding, and nonproliferative myeloid cells achieved maximal levels four days after feeding (Fig 1B and C). The biologic CSF activity in the supernatant one day after refeeding was significantly higher than the value prior to refeeding ($P < .001$). CSF levels decreased over subsequent days, returning to basal levels by day 4 (Fig 1D).

To determine whether the increase in biologic CSF was paralleled by quantitative increases in immunologically measurable CSF, a study was undertaken in which LTBMC supernatant, obtained at daily intervals for 1 week, was simultaneously assayed for CSF by both bioassay and radioimmunoassay. The results showed a prompt rise 24

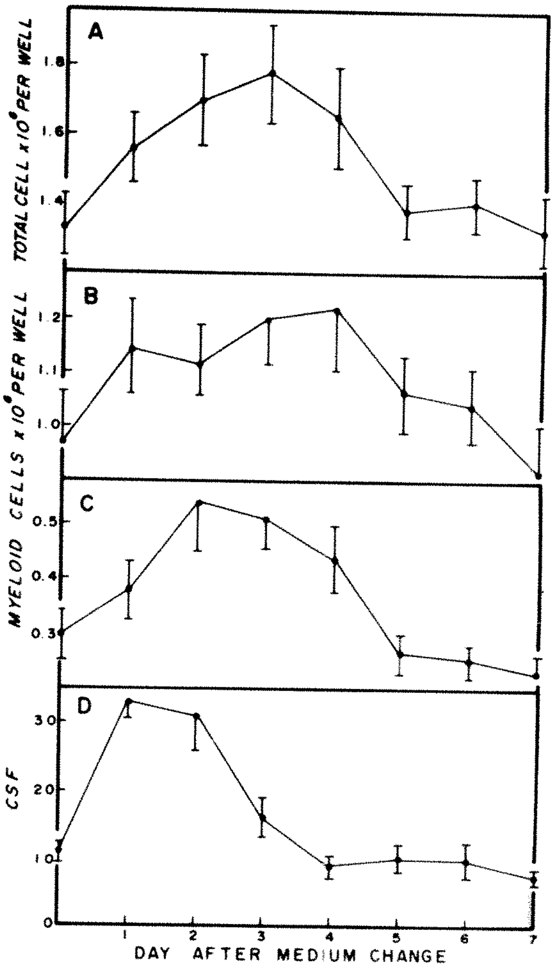

Fig 1. Daily fluctuations in total cell number (A) and in nonproliferative (B) and proliferative (C) myeloid cells in long-term bone marrow culture (LTBMC); biologic colony-stimulating factor (CSF) expressed as CFU-C/10^6 marrow cells (D). Results show daily measurements obtained from six wells prior to and for seven days after medium changes starting 4 weeks after culture initiation. Each value represents the mean of seven separate 1-week studies.

hours after feeding in both biologically active and immunologic CSF (Fig 2). Thereafter, both measurements returned toward basal levels.

In these studies, highly significant increases in CSF occurred prior to a wave of increased granulopoiesis. Previous reports showed that midweek feeding of LTBMCs increased total cell production.[16] We therefore investigated the effect of a midweek medium change four days after feeding and demonstrated a significant increase in total LTBMC cell and myeloid counts three days later (Fig 3). This wave of increased myelopoiesis was preceded by significant increases in biologic CSF that was maximal one day after midweek feeding.

Subsequent studies examined the effect on cell production of adding CSF alone to LTBMCs. In these experiments, three separate CSF preparations were studied. These included the addition of known concentrations of CSF contained in LCM, purified CSF prepared from L cell medium, or CSF contained in tenfold-concentrated supernatant obtained from LTBMCs 24 hours after medium change. In these studies, the refeeding of the fifth week (corresponding to day 7 of the studies described above) was replaced by the addition of 40 μL of the solution containing the CSF being tested. Control cultures received 40 μL of an identical solution that did not contain CSF. In these cultures, significant reductions in total cell numbers per well occurred over the subsequent days (Fig 4). In contrast, when 40 μL of LCM was added to cultures, a significant increase in total cell and myeloid number in each well occurred over the next three days ($P < .001$, Fig 4). A significant increase in total cells and myeloid cells in each well occurred when LCM containing similar levels of CSF was added to LTBMCs four days after refeeding. The effect of adding purified L cell CSF or CSF concentrated from LTBMC supernatant to the cultures is shown in Table 1. With either form of CSF, a significant increase in both total and myeloid cell production occurred ($P < .001$ for L cell:CSF, $P < 0.02$ for concentrated CSF).

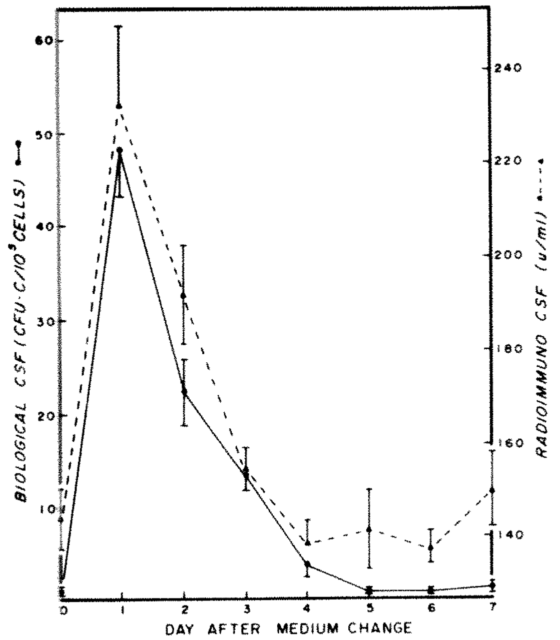

Fig 2. Comparison of biologically measurable colony-stimulating factor (CSF) (●—●) and immunoreactive CSF (▲---▲) in the supernatants of long-term bone marrow cultures (LTBMCs) prior to and for seven days after medium change. Study began 4 weeks after culture initiation. Each value is the mean of CSF levels in six cultures harvested simultaneously for biologic and immunologic assay.

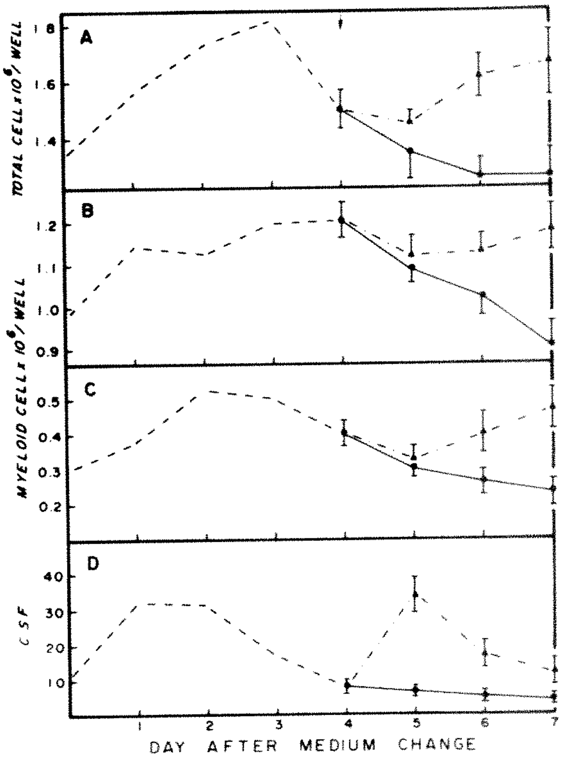

Fig 3. Effect of weekly medium change or midweek feeding on total cell number (A) and on nonproliferative (B) and proliferative (C) myeloid cells in long-term bone marrow cultures (LTMBCs); biologically measurable colony-stimulating factor (CSF) (expressed as CFU-C/10^5 marrow cells) (D). Dotted line for the first four days corresponds to the mean values shown in Fig 1 and is included to allow better interpretation of data. The effect of midweek feeding (▲—·—▲) with corresponding controls (●—●) was undertaken on day 4 and followed until day 7.

In LTBMCs with active hematopoiesis, fluctuations in CSF levels and myeloid cell counts occur when the culture medium is changed. A previous study by Heard and colleagues suggested that the fall in measurable CSF is related to consumption of this material by proliferative myeloid cells.[6] Hence, daily fluctuations of CSF were studied in a LTBMC free of myelopoiesis by examining cultures initiated in the absence of hydrocortisone. Four weeks after initiation, these cultures consisted exclusively of stromal-related cells. In these cultures, minimal fluctuations occurred in daily total cell number or CSF levels (Fig 5). The level of biologically active CSF at the time of medium change in these cultures was significantly higher than in hydrocortisone-containing cultures with active myelopoiesis ($P < .001$).

Following a peak at 24 hours after medium change, CSF

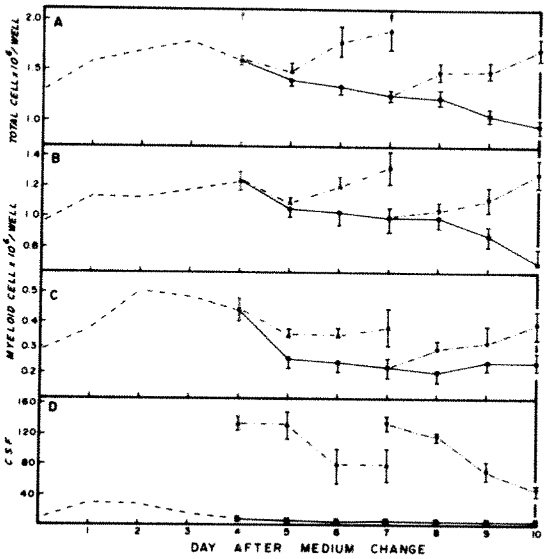

Fig 4. The effect of the addition of 40 μL of lung-conditioned medium (LCM) (containing a colony-stimulating factor (CSF) level of 136.6 ± 10.8 CFU-C/10^5 cells) to long-term bone marrow culture (LTBMC) four days or seven days after medium change. Dotted line for the first four days corresponds to the mean values shown in Fig 1 and is included to allow better interpretation of the data. The addition of LCM on day 4 (▲—·—▲) or day 7 (▼—·—▼) after medium change resulted in significant increases in total cell number (A), and in nonproliferative (B) and proliferative (C) myeloid cells. This increase is contrasted with reduction in cell numbers when control cultures received 40 μL of an identical solution not containing CSF on day 4 or day 7 (●——●). Biologic measurements of CSF (expressed as CFU-C/10^5 marrow cells) were increased in the supernatant on the day that LCM was added to the culture (D).

levels in LTBMCs markedly decreased over the subsequent days. The measured decrease in the biologic CSF level may be due to the presence of an inhibitor of CFU-C growth in the culture. To test this possibility, a biologic CSF assay was made in which the LTBMC supernatant, with an optimal concentration of LCM or LCM added that resulted in a 50% stimulation of CFU-C production, was tested for CFU-C growth. As shown in Fig 6, no inhibitor or promoter of CFU-C growth could be detected in this system.

The effect of adding an antiserum against L cell CSF to LTBMC at the time of medium change was then examined. Preliminary studies showed that a dilution of 1:100 of this antiserum neutralized 100% of the CSF contained in LTBCM supernatant 24 hours after medium change. Studies were made at the time of routine feeding 4 weeks after culture initiation. Antiserum, at a final dilution of 1:100, was added to half the cultures. The remaining cultures received an identical concentration of a control rabbit serum. The presence of antiserum in the medium totally neutralized supernatant CSF levels (Table 2). Despite a decrease in measurable CSF in the supernatant, no inhibition of cell production occurred in LTBMC. In a further study, the effect of adding a higher concentration of antiserum (1:17) to cultures was examined. Even at this level, no decrease in myelopoiesis occurred in cultures despite complete neutralization of supernatant CSF (Table 2).

DISCUSSION

Although CSF is essential for the clonal growth of committed myeloid progenitor cells in vitro, its role in the regulation of myelopoiesis in vitro and in vivo is not completely understood. The presence of CSF is required continually for primitive myeloid progenitor cells to mature into recognizable colonies.[17] Although correlative studies have suggested a relationship between levels of serum CSF and myelopoiesis,[18-20] speculation continues over the in vivo role of CSF. Recent evidence in LTBMC studies provides support for a regulatory role of CSF in myeloid cell proliferation. The results we describe complement the reports of Heard and colleagues and Gualtieri and co-workers, which demonstrated high CSF levels when myelopoiesis was decreased or suppressed and vice versa.[6,7] The method we used allowed examination of the relationship of CSF to myeloid cell production on a day-to-day basis. We demonstrated that weekly or midweek feeding of cultures was followed by a wave of increased myelopoiesis that was invariably preceded

CSF, colony-stimulating factor; LTBMC, long-term bone marrow culture.

Forty microliters of CSF in LCM, purified L cell CSF, or CSF concentrated from LTBMC was added to culture seven days after medium change. Control cultures received 40 μL of an identical solution not containing CSF. The CSF concentration in LCM was 341.5 CFU-C/10^5 cells/mL. CSF concentration for L cell CSF was 381.7, and the concentrated supernatant from LTBMC was 393.5 CFU-C/10^5 cells/mL.

*Cell count × 10^6/well.

†CSF expressed as CFU-C/10^5 bone marrow cells.

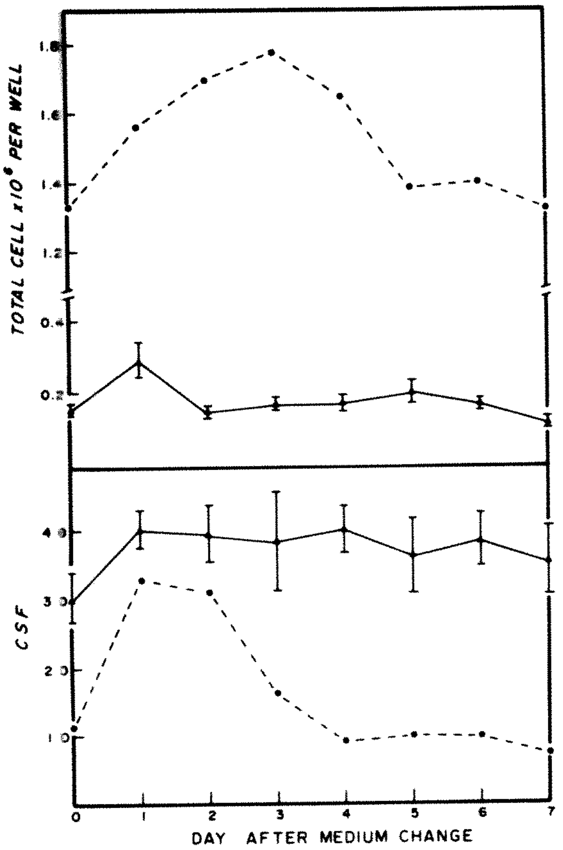

Fig 5. Comparison of daily total cell number (top) and biologic colony-stimulating factor (CSF) (bottom) in long-term bone marrow cultures (LTBMCs) initiated with (●---●) or without hydrocortisone (▲—▲). CSF is expressed as CFU-C/10^5 marrow cells.

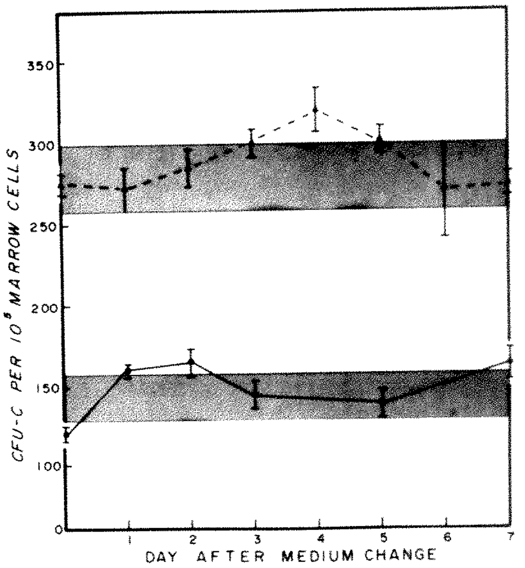

Fig 6. The presence or absence of promoters or inhibitors of colony-stimulating factor (CSF) in supernatant collected from long-term bone marrow cultures (LTBMCs) in Linbro-well cultures prior to and daily for seven days after medium change. Results demonstrated CFU-C production when LTBMC supernatant was cultured with lung-conditioned medium (LCM) that maximally stimulated CFU-C growth (▲---▲) or with LCM that stimulated CFU-C growth to 50% of maximum (●—●). Horizontal bars: mean (± SEM) CFU-C obtained when marrow was cultured for CFU-C with LCM alone.

by significant increases in CSF measured either biologically or immunologically, which strongly suggests a direct cause-and-effect relationship. This finding confirms a recent report showing an increase in CSF following medium change in flask cultures.[21] We believe that the failure to detect significant levels of CSF in culture in early studies is related to the time at which the supernatant was sampled (seven days after medium change).

We also, for the first time, demonstrated that the addition to LTBMCs of high concentrations of various forms of CSF alone (ie, without medium change) caused an increase in myeloid cell production that equaled that which occurred when whole medium was added to the culture. Similar increases in myelopoiesis were observed when the CSF contained in LCM, purified L cell CSF, or CSF concentrated from LTBMCs was added to the culture. This result contrasts to the study of Dexter and Shadduck,[4] who could not demonstrate an effect on myeloid cell production due to the addition of standard or pure L cell CSF to LTBMC. We believe that this is related to the dose of CSF added to culture (120 U/mL in the earlier study as compared with 380 U/mL in this report) and to examination of the culture only seven days after the addition of CSF. If these cultures had been examined daily, the results probably would have been similar to ours. The fact that L cell CSF stimulated myelopoiesis is of additional interest. This finding is not compatible with the belief that L cell CSF stimulates only macrophage proliferation. L cell CSF may also enhance myelopoiesis indirectly by stimulating microenvironmental cells to produce a myeloid cell-specific CSF.

CSF levels were increased in supernatants from LTBMC initiated in the absence of hydrocortisone. These cultures had an established adherent layer but did not produce myeloid precursors. The findings confirm previous reports that CSF levels increase in cultures in response to a reduction of myelopoiesis.[6,7] Consumption and degradation of CSF by proliferating myeloid cells has been reported previously and probably accounts for the lack of day-to-day fluctuations in CSF levels following medium change in these cultures.

Previous studies either did[22] or did not[6] show inhibitors to CSF in the supernatants of LTBMCs. Other researchers demonstrated colony-promoting activity (CPA), which enhances CFU-C production by recruitment of stem cells from a pre-CFU-C compartment.[23] To determine whether either inhibitors or promoters were present in the supernatant of LTBMCs on a day-to-day basis, we measured biologically active CSF in LTBMC supernatants mixed with LCM. This medium contained CSF that, either maximally or at 50% of the maximum, stimulated CFU-C growth in vitro. With this approach, no inhibitor or promoter could be detected. The experimental conditions that we used to seek promoters or inhibitors to myelopoiesis in culture were identical to those used in the previous study.[22] We have no explanation for the discrepancy between our results and the previous report.

Cells in the hematopoietic microenvironment evidently play an important role in the regulation of in vitro and in vivo myelopoiesis.[24] These cells, which include monocytes, macrophages, and fibroblastoid cells synthesize CSF, which in turn stimulates granulopoietic cells to divide. This function is believed to occur locally and to involve a CSF-mediated direct interaction between microenvironmental and myeloid cells. Our results, which demonstrated fluctuation in supernatant CSF that was temporally related to myelopoiesis, raise the possibility that CSF produced by the microenvironment is first excreted into the surrounding medium and then stimulates myeloid precursors. To test this possibility, we performed studies in which anti-CSF serum was added to LTBMC. Anti-CSF neutralized supernatant CSF, yet had no effect on myelopoietic cell production. This result supports the previous observation that the addition of anti-CSF to culture at the time of medium change had no effect on supernatant cell recovery.[4] A likely explanation of our results is that CSF levels in the supernatant must merely reflect CSF function within the microenvironment. This observation supports the concept that CSF acts by a cell–cell interaction between microenvironment and hematopoietic cells. Presumably, CSF in the medium is proportional to the CSF produced. Because CSF production precedes a wave of myelopoiesis, a role for the hormone in myelopoietic regulation is strongly supported. Because exogenous CSF also stimulates myelopoiesis, it too probably can react with microenvironmental cells to stimulate primitive myelopoietic cells to divide. Alternatively, the added CSF may stimulate microenvironmental cells to synthesize endogenous CSF or other factors, which in turn stimulates myelopoiesis. Because increased myelopoiesis occurs when CSF alone (ie, without medium change) is added to cultures, these results also indicate that CSF production rather than nutrient requirement limits the rate of granulopoiesis in LTBMC.

Retinoic Acid Cooperates With Tumor Necrosis Factor and Immune Interferon in Inducing Differentiation and Growth Inhibition of the Human Promyelocytic Leukemic Cell Line HL-60

By Giorgio Trinchieri, Mark Rosen, and Bice Perussia

In this study, we analyzed the effect of tumor necrosis factor (TNF) on retinoic acid (RA)-induced myeloid differentiation of the promyelocytic HL-60 leukemia cell line. We show that low concentrations of the two substances, almost inactive in inducing differentiation when used separately, induce differentiation when added simultaneously to the cell cultures. Cells simultaneously expressing both monocyte/macrophage phenotype (typically induced by TNF) and granulocyte characteristics (typically induced by RA) are induced by a combination of the two factors, indicating that TNF and RA potentiate each other's activity. The results obtained using immune interferon (IFN-γ) in combination with the two inducers suggest that the mechanism of action of TNF and IFN-γ are possibly different. The inhibitory effect of RA on the expression of HLA class I antigens and of the high-affinity Fc receptor is potentiated by TNF but completely reversed by rIFN-γ.
© 1987 by Grune & Stratton, Inc.

LEUKEMIA-DERIVED human myeloid cell lines, such as the promyelocytic HL-60,[1] are often used as models to study terminal differentiation of myelomonocytic cells. Dimethylsulfoxide (DMSO),[2] retinoic acid (RA),[3] and other substances induce HL-60 cells to differentiate along the myeloid lineage, whereas 12-*O*-tetra-decanoyl phorbol-13-acetate (TPA),[4] 1,25-dihydroxyvitamin D_3,[5] and leukocyte products contained in medium conditioned from phytohemagglutinin (PHA)-activated leukocytes (PHA-CM)[6-8] induce them to differentiate into cells with characteristics of monocyte/macrophages. We[9] demonstrated that PHA-CM in which immune interferon (IFN-γ) is neutralized with specific antibodies or antibodies from which IFN-γ has been removed by immune affinity chromatography is less potent than untreated PHA-CM in inducing differentiation of human myeloid cell lines and fresh myeloid leukemia cells. IFN-γ, however, exists in PHA-CM in concentrations insufficient to account for its differentiation-inducing activity, and other factors have been detected in IFN-γ–depleted PHA-CM that synergize with IFN-γ to induce differentiation.[9]

Recently, purification and cloning of the genes for tumor necrosis factor (TNF) and lymphotoxin (LT) have allowed more detailed studies of the biology of these cytotoxins.[10-14] The two cytotoxins also appear to mediate regulatory effects on various cell types, eg, they act as growth factors on fibroblasts[15,16] and regulate proliferation, differentiation, and functions of myelomonocytic cells at all stages of differentiation.[17] In particular, we demonstrated that a soluble factor that inhibits myeloid and erythroid colony formation in vitro is produced by natural killer (NK) cells[18] and has characteristics of TNF, and that LT and IFN-γ, produced by mitogen-activated T cells, act synergistically to block colony formation.[19] We also showed that cytotoxins TNF or LT at concentrations on the order of 10^{-11} mol/L induce monocytic differentiation of human myeloid cell lines[20] and act synergistically with IFN-γ.

The possibility of using inducers of differentiation for the therapy of leukemias or other tumors has recently received considerable interest. Of the many agents that induce differentiation of HL-60 cells, RA has until now been considered one of the inducers of possible therapeutic use because it is active in vitro at physiologic concentrations,[3] induces differentiation of fresh leukemia cells in primary cultures,[21] and is effective in vivo on patients with acute promyelocytic leukemia.[22,23] Cooperation between suboptimal concentrations of RA and the differentiation inducer(s) contained in PHA-CM in inducing differentiation of HL-60 cells have been reported.[24,25] LT[19] and low levels of TNF (G. Trinchieri, M. Rosen, and B. Perussia, unpublished observations) are contained in PHA-CM and, at least in part, are responsible for its differentiation-inducing activity, synergistic with IFN-γ, present in the PHA-CM. In the present study, we analyzed the combined effect of TNF and RA on the differentiation of HL-60 cells. Concentrations of the two substances, almost inactive by themselves, induced most HL-60 cells to differentiate when added simultaneously to the cultures. The combined effect of the two substances powerfully induced cells simultaneously expressing both monocyte/macrophage markers, typically induced by TNF, and granulocyte characteristics, typically induced by RA.

MATERIALS AND METHODS

Monoclonal antibodies. Monoclonal antibodies B9.8, B52.1, B33.1, and B137.17 were produced and characterized in our laboratory; OKM1, 5E9, W6.32, and BBM1 were produced from cell lines obtained from the American Tissue Culture Collection (Rockville, MD); 3G8 was kindly donated by Dr J. Unkeless (Mount Sinai School of Medicine, New York), and KuFc79 was a gift of Dr P. Gambel (Medical College of Virginia). Antibodies B9.8 (IgM,[26]) and OKM1 (IgG2b, anti-C3bi receptor,[27]) react with two distinct antigens expressed on all differentiated neutrophilic granulocytes and monocytes and start to be expressed, during differentiation, at the myelocytic and promyelocytic stages, respectively. Antibody B52.1 (IgM,[8]) reacts with all peripheral blood monocytes and all

α-naphthyl acetate esterase (ANAE)-positive cells in the bone marrow, and cross-competes for binding to monocytes with antibody Mo2.[28] Antibody W6.32 (IgG2a,[29]) reacts with HLA class I antigens, antibody BBM1 (IgG2a,[30]) reacts with β_2-microglobulin, and antibody B33.1 (IgG2a,[31]) reacts with HLA class II antigens. Antibody 5E9 (IgG1,[32]) reacts with the transferrin receptor. Antibody 3G8 (IgG1,[33]) reacts with a surface molecule of mol wt 50,000 to 72,000 identified as the low-affinity receptor for aggregated IgG on neutrophilic granulocytes, NK cells, and macrophages. The mouse monoclonal IgG2a B137.17 is an Ig of unknown specificity selected on the basis of its high-affinity binding, in monomeric form, to the IFN-γ–inducible FcR on monocyte and myeloid cell lines.[34] The binding of B137.17 to cells is Fc fragment dependent, and is blocked by monomeric human IgG1 and IgG3 and murine IgG2a and IgG3. Sepharose-linked B137.17 precipitates from human monocytes and myeloid cell lines a molecule of mol wt 70,000, identified as the high-affinity FcR for monomeric IgG. Antibody KuFc79 (IgG2b,[35]) reacts with a 42,000-dalton FcR species present on monocytes, granulocytes, and B cells.

Cytokine preparations. Purified human recombinant IFN-γ (rIFN-γ) from *Escherichia coli* was kindly supplied by Dr H. M. Shepard (Genentech, South San Francisco) and has an antiviral activity titer of 7×10^7 U/mg of HeLa cells. Two preparations of human recombinant TNF (rTNF) were used in this study with identical results: one (90% pure, 10^7 U/mg as tested on L-929, α subline, cells) was kindly supplied by Dr J. S. Price (Cetus, Emeryville, CA), and the other (electrophoretically homogeneous, 5×10^7 U/mg) was supplied by Dr H. M. Shepard (Genentech).

Induction of myeloid cell lines. HL-60 cells were seeded at 1.5×10^5 cells/mL in RPMI 1640 medium (Flow Laboratories, Rockville, MD) supplemented with 15% fetal bovine serum (FBS). The various inducers of differentiation were present throughout the culture period. All-*trans*-RA (Sigma) was dissolved in ethanol (0.3 mg/mL).

Cytochemistry. Staining for ANAE was according to Platt.[36] Ability of the cells to reduce nitroblue tetrazolium (NBT, Sigma) was determined by mixing on a microscope slide 1 vol of cells in medium (5×10^6 cells/mL) and 1 vol of 1 mg/mL of NBT in NaCl 0.15 mol/L. After a 30-minute incubation at 37°C in a humidified atmosphere, slides were dried, stained with Wright's-Giemsa, and the percentage of cells containing blue-black formazan deposits was scored from at least 200 cells.

Indirect immunofluorescence, cell cycle analysis, and ^{3}H-thymidine (^{3}H-TdR) incorporation. Indirect immunofluorescence (flow cytometry), cell cycle analysis by staining of DNA using propidium iodide, and ^{3}H-TdR incorporation, were performed as previously described in detail.[20]

RESULTS

Morphological changes in HL-60 cells cultured with RA and TNF. When cultured in 300 nmol/L of RA for five days, most HL-60 cells acquired the morphology of mature myeloid cells, from myelocytes to polymorphonuclear cells (Fig 1C). Little or no morphological differentiation was observed with 10 nmol/L of RA (Fig 1B). Treatment of HL-60 cells with rTNF (10 U/mL) resulted in minimal morphological changes: TNF-treated HL-60 cells (Fig 1D) became smaller and more irregular, and the proportion of cells with nucleoli and primary granules was lower than in control untreated cultures. In cultures with 10 nmol/L of RA and 10 U/mL of rTNF, with or without rIFN-γ, a large proportion of HL-60 cells appeared to have mature myeloid morphology, including polymorphonucleated cells (Fig 1E). Addition of 10 U/mL of rTNF to HL-60 cell cultures in the presence of 300 nmol/L enhanced the formation of cells with mature myeloid morphology: Almost all HL-60 cells on day 5 of culture acquired the morphology of polymorphonuclear granulocytes (Fig 1F).

Induction of differentiation of HL-60 cells by TNF and RA. As previously shown,[20] a proportion of HL-60 cells cultured for five days in the presence of TNF expressed the monocyte-specific antigen recognized by antibody B52.1, the myelomonocytic antigen OKM1 at higher density than untreated cells, ANAE activity, and ability to reduce NBT (Fig 2 and Table 1). The expression of the myelomonocytic antigen recognized by antibody B9.8 was also increased (not shown), whereas the proportion of cells bearing transferrin-

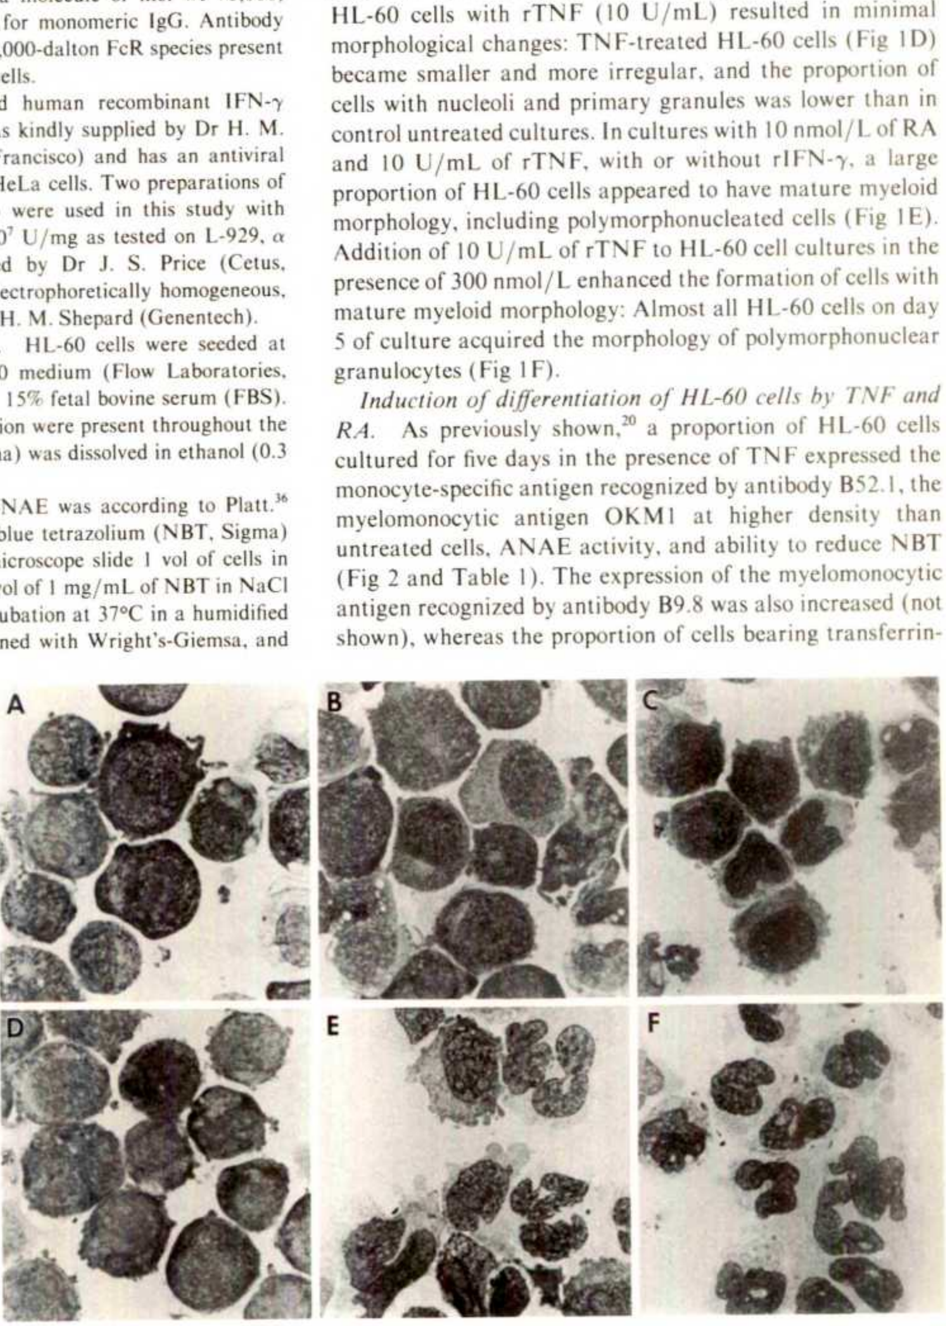

Fig 1. Morphology of HL-60 cells cultured in the presence of retinoic acid (RA) and/or recombinant tumor necrosis factor (rTNF). Cytocentrifuge smears were prepared from HL-60 cells, cultured for five days in the presence of the inducers, and stained with May-Grunwald-Giemsa. HL-60 cells were cultured in: (A) culture medium, or in culture medium supplemented with (B) 10 nmol/L of RA; (C) 300 nmol/L of RA; (D) 10 U/mL of rTNF; (E) 10 U/mL of rTNF and 10 nmol/L of RA; (F) 10 U/mL of rTNF and 300 nmol/L of RA. (Magnification ×690.)

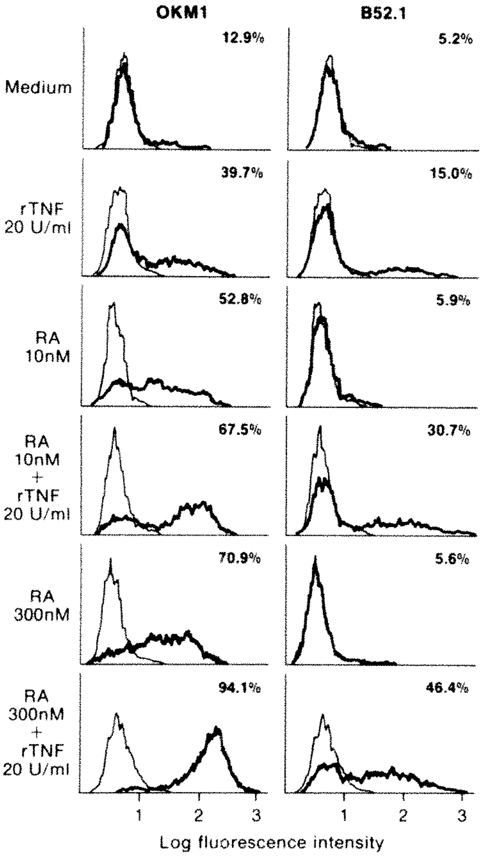

Fig 2. Expression of surface antigens on HL-60 cells cultured with retinoic acid (RA) and/or recombinant tumor necrosis factor (rTNF). The phenotype of HL-60 cells, cultured for five days with the addition of the indicated inducers, was studied using the indicated antibodies. On the histograms, the *x* axis represents the intensity of green fluorescence on an exponential scale; the *y* axis represents the number of cells; the thin line histograms represent the fluorescence of control cells in the absence of the monoclonal antibodies; the thick line histograms represent the fluorescence of the cells stained with the indicated monoclonal antibodies. The values in the top right corner of each histogram are the percentages of positive cells, calculated as described in the Materials and Methods section. Results are representative of six experiments with comparable results.

receptor, as detected using antibody 5E9, was slightly decreased (Fig 3). rIFN-γ alone (100 U/mL) had only a minimal effect on the expression of monocytic or myelomonocytic antigens and on ANAE or NBT reduction activities (Figs 2 and 3B, Table 1). Addition of rIFN-γ to TNF potentiated its ability to induce differentiation markers in HL-60 cells: previously reported experiments[20] demonstrated that the two factors act synergistically. Most HL-60 cells were induced by 300 nmol/L of RA to express the myelomonocytic antigens recognized by antibodies OKM1 (Fig 2) and B9.8 (not shown); no induction was observed using 10 nmol/L of RA; however, 10 nmol/L of RA potentiated the ability of rTNF, alone or in combination with rIFN-γ, to induce the two antigens. The number of HL-60 cells reducing NBT was modestly increased by 10 and 300 nmol/L of RA; RA, at both concentrations, acted synergistically with rTNF and rIFN-γ in inducing NBT reduction activity in

ANAE, α-naphthyl acetate esterase; rTNF, recombinant tumor necrosis factor; rIFN-γ, human recombinant interferon-γ, RA, retinoic acid; NBT, nitroblue tetrazolium.

HL-60 cells were cultured for five days with the indicated inducers and analyzed for ANAE and NBT reduction activities as described. Results are from one representative experiment of four experiments performed with similar results.

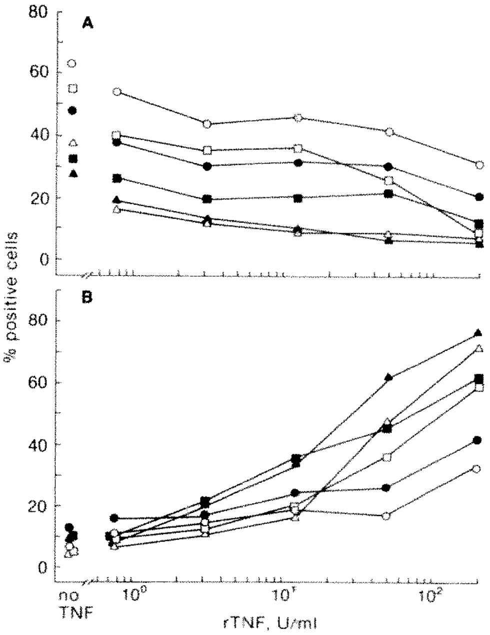

Fig 3. Synergistic effect of recombinant tumor necrosis factor (rTNF), human recombinant interferon-γ (rIFN-γ), and retinoic acid (RA) on the expression of the transferrin receptor, detected by antibody 5E9 (A), and of the monocyte-specific antigen detected by antibody B52.1 (B). HL-60 cells were cultured for five days with the indicated concentrations of rTNF in medium containing or not containing RA and rIFN-γ, washed, and tested by indirect immunofluorescence (flow cytometry) for expression of the indicated surface markers. HL-60 cells were cultured in medium containing: neither RA nor rIFN-γ (○); 100 U/mL of rIFN-γ (●); 10 nmol/L of RA (□); 10 nmol/L of RA and 100 U/mL of rIFN-γ (■) 300 nmol/L of RA (△); and 300 nmol/L of RA and 100 U/mL of rIFN-γ (▲).

HL-60 cells (Table 1). The expression of transferrin receptor as detected by antibody 5E9 (Fig 3A) was decreased by RA, and, more efficiently, by RA and rTNF; no synergism between rIFN-γ and RA in inhibiting transferrin receptor expression was observed. Finally, two monocytic markers, ie, the antigen recognized by antibody B52.1 (Fig 2) and ANAE activity (Table 1), were not induced by RA alone, but RA, at both 10 and 300 nmol/L, strongly potentiated the ability of rTNF, alone or in combination with rIFN-γ, to induce these markers in HL-60 cells. rTNF, at doses as low as 1 U/mL, significantly potentiated the effect of RA in reducing expression of transferrin receptor (Fig 3A), whereas the effect on the expression of B52.1 antigens was observed at rTNF doses $\geq$3 U/mL (Fig 3B). The effect on the expression of the two antigens was dose-dependent up to the highest concentration tested (200 U/mL of rTNF) and was potentiated by the presence of 100 U/mL of rIFN-γ (Fig 3). The analysis of these quantitative data demonstrated that the effects of the combination of RA and TNF on surface antigens expression are synergistic. A similar conclusion was derived from dose–response experiments (not shown) on the induction of ANAE activity and NBT reduction activity.

Cooperation between RA and rTNF in inhibiting proliferation of HL-60 cells. RA at 300 nmol/L almost completely suppressed ^{3}H-TdR incorporation by HL-60 cells cultured for five days (Table 2). At 10 nmol/L of RA, the inhibition was partial but became almost complete in the presence of rTNF. rIFN-γ did not potentiate the ability of RA to suppress ^{3}H-TdR incorporation in these cultures. Cell cycle analysis of proliferation revealed that almost no HL-60 cells were in S phase on day 5 of culture in the presence of 300 nmol/L of RA, rTNF, and rIFN-γ, but that a proportion of cells was in G2 phase after culture in the presence of 300 nmol/L of RA. At 10 nmol/L of RA, only a modest effect was observed on the distribution of the cells in the cell cycle, but addition of rTNF produced a profound decrease of cells in S phase, with some cells remaining in G2 phase, as was observed at higher RA concentrations.

Expression of different FcR types and HLA class I antigens on HL-60 cells induced with rTNF, rIFN-γ, and RA. The results of the analysis of FcR expression on HL-60 cells during differentiation are shown in Table 3. The low-affinity FcR of neutrophils, NK cells, and macrophages recognized by antibody 3G8 was poorly induced by rTNF, rIFN-γ, or RA alone, but was significantly induced by the combination of RA with rTNF or rIFN-γ. When HL-60 cells were cultured in the presence of the three inducers together, 3G8 antigen was induced in almost 50% of the cells. The expression of the 42,000-dalton FcR of neutrophils, monocytes, and B cells recognized by antibody KuFc79 was not significantly affected by rTNF and rIFN-γ, but the proportion of positive cells was strongly reduced in cultures with 10 or 300 nmol/L of RA. The inhibition of KuFc79 antigen expression by RA was partially reversed when either rTNF or rIFN-γ was present in the cultures, and the reversal was even greater when both were present. Expression of the high-affinity FcR for monomeric IgG, detected by binding of monoclonal IgG2a B137.17, was strongly enhanced by rIFN-γ but not by rTNF (Table 3). rTNF, however, potentiated the effect of rIFN-γ in inducing the receptor. RA, at 10 or 300 nmol/L, strongly suppressed the expression of the high-affinity FcR; rTNF potentiated the inhibitory effect of RA on induction of this FcR, whereas rIFN-γ completely reversed it.

Both rTNF and rIFN-γ increased expression of HLA class I antigens (as detected by antibody W6.32) and β_2-microglobulin (as detected by antibody BBM1) on HL-60 cells when used alone; a much better induction was observed in most but not all experiments when a combination of the two cytokines was used (not shown). RA at 300 but not at 10 nmol/L decreased expression of HLA class I antigens on HL-60 cells. rTNF, which by itself increases HLA class I antigen expression on HL-60 cells, potentiated the inhibitory effect of 300 nmol/L of RA and decreased HLA class I antigens expression in the presence of 10 nmol/L of RA. Unlike rTNF, rIFN-γ strongly increased HLA class I antigen expression in the presence of either 10 or 300 nmol/L of RA.

DISCUSSION

RA is a potent inducer of myeloid differentiation in vitro of promyelocytic cell lines and of fresh leukemic cells from patients with acute promyelocytic M3 leukemia.[34-36] The

Table 2. Effect of rTNF, rIFN-γ, and RA on the Proliferation of HL-60 Cells

Inducer	^{3}H-TdR Uptake cpm (% Inhibition)	Percentage of Cells in		
		G0/G1	S	G2/M

RA, 300 nmol/L	2,041 (97.9)	80.9	7.0	12.0

Abbreviations as in Table 1.

HL-60 cells were cultured for five days with the indicated inducers. To evaluate ^{3}H-TdR uptake, cells were cultured in 96-well flat-bottomed microtiter plates (initial concentration 2 × 10^4 cells/well in 200 μL). Cultures were pulsed with ^{3}H-TdR 1 μCi/well for six hours before harvesting. For cell cycle analysis (flow cytometry analysis of propidium iodide (PI)-stained cells), cells were cultured in flasks (initial concentration 1.5 × 10^5 cells/mL). Data are from one representative experiment of three experiments performed with similar results.

Abbreviations as in Table 1.

[*] HL-60 cells were cultured for five days with rTNF (20 U/mL), rIFN-γ (100 U/mL), RA (300 or 10 nmol/L), or a combination of the various factors. Results are representative of six experiments with comparable results.

[†] Percentage of positive cells as detected by indirect immunofluorescence (flow cytometry). The threshold fluorescence intensity at which 99% of the cells without first antibody added were negative was determined on HL-60 cells cultured in the absence of differentiation inducers and used for all the samples.

[‡] Numbers in parentheses indicate average intensity of fluorescence (on an arbitrary linear scale from 1 to 200) of positive cells.

human histiocytic cell line U937 is also induced to differentiate by RA,[37] but the human erythromyeloid leukemic cell line K562 and the myeloblastic leukemic cell line KG1[38] are not. RA, however, is a potent inhibitor of clonal growth not only of the HL-60 line, but also of the KG1 cell line that is not induced to differentiate by it,[38] and of leukemic cells freshly obtained from chronic myelogenous leukemia (CML) or from acute myelogenous leukemia (AML) patients[38] of M1, M2, and M3 stages. The concentrations of RA active in vitro in inducing differentiation of fresh leukemic cells or leukemia-derived cell lines as well as those inducing inhibition of clonal growth are in the order of 10^{-9} to 10^{-8} mol/L and are obtainable in vivo without prohibitive side effects.[22,23,39] In addition, RA is not toxic to normal hematopoietic precursor cells, but, on the contrary, significantly enhances the growth of normal hematopoietic colonies.[40,41] Other potent inducers of differentiation of myeloid cells such as TNF have, unlike RA, high systemic toxicity and are potent inhibitors of proliferation of both normal and leukemic hematopoietic progenitor cells, as well as of other cell types.[18] These activities limit their therapeutic potential for treatment of leukemias or other malignancies. The synergistic interaction of RA with other differentiation-inducing factors offer the promising possibility to induce differentiation and growth inhibition of leukemic cells at concentrations of either factor that might not affect normal precursor cells or have a generalized toxic effect.

RA is strongly synergistic with TNF in inducing differentiation of HL-60 cells, even at concentrations of 10^{-8} mol/L which, in the absence of TNF, are ineffective in inducing differentiation. The combination of 10^{8} mol/L of RA and 10^{-10} mol/L of TNF halts growth of HL-60 cells and induces expression of differentiation markers in almost all cells. An at least additive effect of IFN-γ and RA in inducing differentiation of U937 cells has been reported by Gullberg and colleagues.[42] The synergy of IFN-γ with RA is not as great as that of TNF and RA in inducing differentiation or growth inhibition of HL-60 cells, but the combination of the three factors often induces the most complete differentiation.

When TNF is added to HL-60 cells cultured with doses of RA able to induce myeloid differentiation (3×10^{-7} mol/L), the generation of mature myeloid cell types is not prevented and the induced cells, although expressing specific monocytic markers such as ANAE and B52.1 antigen, have typical mature myeloid morphology. When TNF is added with 10^{-8} mol/L of RA, a concentration unable to induce morphological maturation of HL-60 cells, mature myeloid cell types are induced in the cultures. Thus, not only does RA potentiate the monocytic differentiation induced by TNF, but TNF potentiates the myeloid differentiation induced by RA, and cells with intermediate myelomonocytic characteristics are generated. Analogously, B52.1 monocyte-specific antigen expression is induced on HL-60 cells during the myeloid differentiation induced by DMSO[8] but not by RA, and intermediate myelomonocytic characteristics are induced in a subset of chronic myelogenous leukemia cells by PHA-CM and IFN-γ.[7] This lineage ambiguity is not peculiar to leukemic cells, because similar results have been obtained with normal bone marrow immature myeloid cells when forced to differentiate in vitro.[7]

The interplay between TNF, IFN-γ, and RA in regulating expression of differentiation markers on HL-60 cells is best illustrated by the effect on HLA class I antigens and on the different types of Fc receptor. Both TNF and IFN-γ increase expression of HLA class I antigens, as previously described with other cell types.[43] The mechanism of action of the two cytokines is probably different, however, as suggested by results obtained in experiments in which HL-60 cells were tested with RA added. RA alone drastically decreases the expression of HLA class I antigens and TNF potentiates this inhibitory effect, whereas IFN-γ completely reverses it, inducing high expression of HLA class I antigens on most cells. The increased expression of these antigens during monocytic differentiation and their decreased expression during myeloid differentiation parallel the high and low expression of HLA class I antigens on mature monocyte and granulocytes, respectively. The pattern of high-affinity FcR induction on HL-60 cells by the differentiation agents is almost identical to that of HLA class I antigens. Again, the induction of high-affinity FcR during monocytic differentiation of HL-60 cells and its decreased expression during myeloid differentiation parallel the distribution of the FcR on normal differentiated cells, ie, high-level expression on monocytes and lack of expression on granulocytes, although in the latter cell type the high-affinity FcR can be induced by IFN-γ.[34,44] The low-affinity FcR present on neutrophils but not on monocytes, as detected by antibody 3G8,[33] is expressed at higher levels on HL-60 cells when the myeloid differentiation induced by RA is potentiated by TNF. Expression of a third type of FcR recognized by antibody KuFc79[35] during the differentiation of HL-60 cells is independent of that of both the high-affinity and low-affinity FcR detected with IgG2a B137.17 and with antibody 3G8, respectively.

The synergism of TNF with RA is similar to that reported by Olsson and colleagues for PHA-CM[25] and for the differentiation-inducing factor purified from the HUT-102 cell line.[45] LT and, in some preparations, TNF, are responsible, at least in part, for the differentiation-inducing activity, synergistic with RA, present in PHA-CM,[19] whereas the differentiation factor produced by HUT-102 cells seems to be distinct from both LT and TNF on the basis of its biochemical characteristics.[45] Understanding of the biochemical mechanism of the synergistic effect between TNF and RA might furnish important information on the regulation of growth and differentiation of normal and leukemic hematopoietic cells. To evaluate the therapeutic potential of the combined effect of the two inducers, it will be important to evaluate whether the combined substances affect normal hematopoietic precursor cells in vitro and whether leukemic cell types, not affected by RA or TNF alone, are induced to differentiate and lose their proliferative ability with the combined treatment.

Pattern of Expression of HLA-DR and HLA-DQ Antigens and mRNA in Myeloid Differentiation

By Thomas T. Amatruda III, Roger Bohman, John Ranyard, and H. Phillip Koeffler

We examined the expression of HLA-DR and HLA-DQ antigens and mRNA from myeloid and lymphoid cells obtained from normal volunteers and established cell lines. Cytofluorometric analysis and immunoprecipitation were performed using murine monoclonal antibodies specific for HLA-DR (L-243) and HLA-DQ (Leu 10). The expression of mRNA for HLA-DR and HLA-DQ chains was determined by Northern blot and RNA dot-blot analysis. Lymphoid cell lines expressed both HLA-DR and HLA-DQ antigens, with consistently higher levels of expression of DR. Myeloid cell lines of early myeloblast or bipotent (myeloid-erythroid) phenotype (KG-1, KG-1a, HEL) expressed HLA-DR at high levels, whereas cell lines manifesting a greater degree of myeloid maturation (ML-3, HL-60, U937) expressed DR at low or undetectable levels. The HLA-DQ antigen was expressed at low levels on the surface of KG-1 and KG-1a cells but was not detectable on other myeloid cell lines. The expression of mRNA for HLA-DR and HLA-DQ chains paralleled the pattern of expression of the respective antigens. The HL-60 and U-937 cells stimulated to differentiate in vitro to macrophages with 1,25 dihydroxyvitamin D_3 [1, $25(OH)_2D_3$] were induced to express detectable levels of HLA-DR antigens. Exposure to γ-interferon (γ-IFN) increased the expression of HLA-DR antigens by all myeloid cell lines. Induction of differentiation in vitro with either $1,25(OH)_2D_3$ or dimethyl sulfoxide potentiated this effect of γ-IFN. Expression of the HLA-DQ antigens was increased on KG-1 myeloblasts after exposure to γ-IFN. HLA-DQ expression could not be detected on other myeloid cell lines after exposure to γ-IFN, nor was HLA-DQ expression stimulated by γ-IFN after HL-60 and U-937 cells were induced to differentiate to macrophagelike cells in vitro. These results provide additional evidence that expression of the HLA-DR and HLA-DQ genes may be independently regulated in human myeloid cells.

ALTHOUGH EXPRESSION of MHC class I antigens is ubiquitous on murine and human cells, the pattern of expression of MHC class II antigens is tissue-specific and varies during differentiation. In humans, hematopoietic precursor cells express HLA-DR antigens but their mature progeny do not, with the exception of macrophages.[1-6] Expression of the other class II antigens DQ (DC, DS, MB) and SB has been less completely characterized. In previous studies on myeloid cells, expression of DQ antigens has apparently been at lower levels than DR expression.[7-9]

Expression of MHC class II antigens by monocytes and macrophages is of functional significance because these cells act as antigen-presenting cells (APCs) in generation of the immune response.[10-12] Antigen-presenting cells are characterized by their ability to act as accessory cells in stimulation of T cell proliferation in vitro and generation of antigen-specific T cell populations in vivo. These functions require the expression of appropriate MHC class II antigens, in addition to other properties specific to reticuloendothelial cells, such as phagocytosis and synthesis of degradative enzyme systems. The MHC type II antigens on the monocyte surface may play a role as a specific binding site for the T cell antigen receptor.[13] Neither immature myeloid cells nor cells from human myeloid cell lines can function as APCs, although cells from myeloid lines may acquire the ability to stimulate T cell proliferation after differentiation of these cells in vitro.[14]

We previously reported that cells of a human promyelocytic leukemia cell line, HL-60, are induced to express HLA-DR antigen by exposure to recombinant human γ-interferon γ-IFN.[15] These cells failed to express detectable levels of HLA-DQ (DC) antigen or mRNA. We and others demonstrated that ~50% of human peripheral blood monocytes are discordant in expression of HLA-DR and HLA-DQ (HLA-DR+, HLA-DQ−).[7,8,15-17] Exposure of monocytes to γ-IFN restored expression of HLA-DR and DQ to a variable extent. Taken together, these results suggest that the expression of HLA-DR may be independently regulated in human myeloid cells.

In the present study, we examined the pattern of expression of HLA-DR and HLA-DQ antigens and mRNA in lymphoid and myeloid cell lines at several stages of differentiation. In addition, we used the myeloid cell lines to study the ontogeny of MHC class II antigen expression induced by γ-IFN.

MATERIALS AND METHODS

RNA isolation, hybridization, and autoradiography. Hematopoietic cells were homogenized in guanidine thiocyanate (Eastman Kodak, Rochester, NY), and RNA from the homogenate was isolated by centrifugation through a cesium chloride cushion as previously described.[18] The poly (A)-containing RNA was enriched by oligo (dT)-cellulose chromatography.[19] Five micrograms of mRNA from each cell type were treated with 20 mmol/L of methyl mercuric hydroxide and electrophoresed in a 1.1% agarose/formaldehyde gel buffered with MOPS. Subsequently, the gel was photographed, equilibrated in 20 × SSC (standard saline citrate; 3 mol/L of NaCl, 0.3 mol/L of Na acetate, pH 6.8) for one hour with gentle rocking, transferred to Zetaprobe nylon membrane (Biorad, Richmond, CA) using 10 × SSC, prehybridized and hybridized to specific cDNA probes.[20,21] The cDNA probes were nick-translated[22]

and used at a specific activity $>10^8$ cpm/μg. Hybridized filters were washed in 2 × SSC at room temperature, and in 2×, 1×, 0.5× and 0.1 × SSC containing 0.1% sodium dodecyl sulfate (SDS) at 68°C for 10 minutes each. The filters were exposed to x-ray film (Kodak XAR-5) for varying lengths of time at −70°C with an intensifying screen (DuPont, Wilmington, DE). Size of hybridizing RNA fragments was determined by comparison with 28S and 18S ribosomal RNA bands.[23] To reuse Zetaprobe blots, the first probe was eluted by washing the filter in 0.1 × SSC with 0.1% SDS at 95°C for two 20-minute washes. The filter was autoradiographed to document removal of probe, and a second hybridization was performed. The relative intensity of hybridization of the cDNA probes to RNA blots was quantitated by laser densitometry, using a Joyce-Loeble densitometer.

The cDNA clones used to probe RNA blots were described previously. The cDNA from tubulin[24] was generously provided by W. Salser. Probes for the HLA-DR α chain were pHLA DR α and p-II-α-1, generously provided by B. Mach and colleagues[25] and D. Larhammar and colleagues,[26] respectively. The probe for the HLA-DQ α chain was pDCH1, generously provided by C. Auffray and co-workers.[27] With our hybridization and rinsing conditions, the probes for HLA-DR α and HLA-DQ α bind to distinct populations of mRNA.[28,29]

Immunofluorescence. Expression of HLA-D antigens on individual cells was determined by indirect immunofluorescence after exposure of cells to murine monoclonal antibodies and fluorescein-coupled $(\text{FAb}')_2$ anti-mouse antibody (FITC-anti-mouse). The murine monoclonal antibodies used in this study have been well characterized. The L243 antibody (IgG2a)[30] (generously provided by T. Meeker and R. Levy) reacts with a nonpolymorphic region of the HLA-DR antigen. The Leu 10 antibody (IgG1)[31] (obtained from Becton Dickinson, Mountain View, CA) reacts with the HLA-DQ antigen on cells with DR allotypes 1,2,4,5,6,8,9, and w10.[32] Control antibodies were a murine myeloma IgG2a protein (Coulter Diagnostics, Hialeah, FL) that does not react with human cells and Leu 5 (IgG1, Becton Dickinson) that does not bind to myeloid cells. The FITC anti-mouse antibody was obtained from Cappel Laboratories (Downington, PA).

Cells were prepared for immunofluorescence studies by washing in Dulbecco's phosphate-buffered saline (PBS) containing 2% heat-inactivated fetal calf serum (FCS) and 0.1% azide (PBS-A), at 4°C. Aliquots of 1 to 3 × 10^6 cells were incubated with murine monoclonal antibody, diluted in 100 μL of PBS-A, for one hour at 4°C, rinsed three times in PBS-A, and then incubated with FITC anti-mouse antibody for 30 minutes. Cells were washed in PBS-A, and immunofluorescence was measured. The following measurements were obtained for each sample of cells: autofluorescence, immunofluorescence after exposure to FITC anti-mouse antibody alone, indirect immunofluorescence after exposure to a control murine monoclonal antibody, and indirect immunofluorescence after exposure to a murine monoclonal antibody directed against one of the HLA-D antigens. Specific binding of antibodies directed against the HLA-DR antigens was determined in relation to binding of the control murine monoclonal antibody of the same isotype. Autofluorescence and binding of FITC anti-mouse antibody alone was always equal to or less than the binding of control antibody. Each experiment was repeated two to four times. In pilot experiments, binding of the Leu 5 control antibody to myeloid cells was not different than binding of the FITC anti-mouse antibody alone. Therefore, binding of the Leu 10 antibody was measured relative to the FITC anti-mouse antibody.

Preliminary saturation studies were performed on ME and Raji cells (Table 1), and showed that an antibody dilution of 1:20 of either Leu 10 or L243 (10 μg/mL) was sufficient to produce maximal cell fluorescence. This concentration of primary antibody was used in all experiments. The second antibody was also used at saturating concentrations (100 μg/mL).

	100	157	76
	300	157	79

*Raji cells were preincubated with L243 antibody, 10 μg/mL.

The effect of blocking the Fc receptors with excess human IgG was studied using HL-60 cells induced to differentiate with DMSO and γ-IFN.[33] Aliquots of 10^6 cells were incubated in a volume of 100 μL with L243 alone [50 μg/mL (300 nm)], or L243 followed by human IgG (Cappel)[2,400 μg/mL (15 μmol/L)]. Each incubation was for one hour at 4°C, and cells were rinsed three times in PBS-A after each incubation. Cells were then incubated with FITC anti-mouse antibody, and immunofluorescence was measured.

Flow cytometry. Immunofluorescence was analyzed on the EPICS V Cell Sorter (Coulter Electronics) coupled with an Innova 90 Laser (Coherent). Samples were excited with the 488 γ wavelength, and fluorescence was obtained on a minimum of 20,000 cells gated from the forward-angle light-scatter profile.[34] Dead cells were excluded from analysis by setting an appropriate threshold trigger on low forward-angle light-scattering.[35] The distribution of cells as a function of the log fluorescence intensity was determined for each sample of cells. Because of differences in autofluorescence, in amounts of antigen expressed, and in percentage of positive cells in the various samples, the cytofluorometric data were also normalized to allow comparison of the relative levels of antigen expression. Normalization involved converting the data to a linear function, determining the median from the distribution, and multiplying this by the percentage of positive cells in each population. In this phase of the study, fluorescence of cells exposed to FITC goat anti-mouse antibody alone was considered background. This method gives a quantitative estimate of the level of antigen expression by a population of cells[36] (Tables 2 and 3).

Pulse-chase labeling of HLA-DR antigens. Raji or KG-1 cells were labeled by incubation for three hours with ^{35}S methionine (100 μCi/mL, 350 mCi/mmol/L, Amersham, Arlington Heights, IL) in methionine-deficient α medium (α-modified Eagle's medium, Flow Laboratories). Cells were washed three times in α medium containing 2 mmol/L of unlabeled methionine and resuspended at a density of 10^6 cells in α medium containing 10% FCS and 1 mmol/L of methionine. Cells were harvested at various times, and the incorporation of label into HLA-DR antigens was measured by immunoprecipitation and autoradiography.

Immunoprecipitation of HLA-DR antigens was performed by

making cell lysates, incubating cell lysates with L-243 antibody, and precipitating immune complexes with protein A agarose (Sigma, St Louis.[37] To make the cell lysates, the labeled cells were resuspended in lysing buffer [0.4% NP-40, 0.4% Na deoxycholic acid, 300 mmol/L of NaCl, 10 mmol/L of EDTA, 100 mmol/L of Tris (pH 7.5), 2 mg/mL of bovine serum albumin (BSA), and 1 mmol/L of phenylmethylsulfonylfluoride, PMSF), and mechanically disrupted. Lysates were centrifuged 10 minutes at 12,000 g, 4°C, and diluted with an equal volume of immunoprecipitation buffer (PBS containing BSA 10 mg/mL, methionine 2 mg/mL, *N*-lauroyl sarcosine 0.1%, pH 7.4). Samples were cleared by mixing with 20 μL of a suspension (1:1) of (protein A agarose:immunoprecipitation buffer), incubating for 15 minutes at 4°C, and centrifuging at 12,000 g for 2 minutes. The supernatant was mixed with 10 μg of L-243 antibody and incubated overnight at 4°C with gentle rocking. Immune complexes were immunoprecipitated by adding protein A agarose to the samples, incubating for 30 minutes, and centrifuging for two minutes at 12,000 g. The pellet was washed five times in PBS containing 0.1% *N*-lauroyl sarcosine, pH 7.4. Immune complexes were denatured by boiling for five minutes in SDS sample buffer (1% SDS, 10% β-mercaptoethanol, 62.5 mmol/L of Tris (pH 6.8), 20% glycerol, bromphenol blue), and analyzed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE).[38] Electrophoresis was performed on a 10% polyacrylamide gel containing SDS, at a constant

current of 20 mA. Gels were prepared for fluorography with ENHANCE (New England Nuclear, Boston) according to the manufacturer's instructions. Autoradiograms were performed as described above, except that ^{35}S autoradiograms were performed with preflashed X-ray film. The intensity of protein bands was quantitated by laser densitometry.

Cells and culture conditions. Myeloid and lymphoid cell lines were cultured in α medium supplemented with 10% FCS (Irvine Scientific, Santa Ana, CA) and 100 U/mL of penicillin-streptomycin (Irvine Scientific), in a 5% CO_2 atmosphere. Cultures were divided every five days to maintain a density $<10^6$ cells/mL. Pulmonary alveolar macrophages (PAM) and peripheral blood cells were obtained from normal volunteers. Peripheral blood mononuclear cells and polymorphonuclear leucocytes were isolated by buoyant-density centrifugation.[39] To enrich for either PAM or PBM, cells were placed in 75-cm^2 plastic flasks containing α medium with 10% FCS. Nonadherent cells were removed from the flasks after four and 24 hours of culture. More than 95% of the adherent cells contained strong α-naphthyl acetate esterase activity, an enzyme that exists in monocytes and macrophages but not in lymphocytes or granulocytes. The T lymphocytes were isolated from the mononuclear fraction of peripheral blood by sheep E rosetting.

Mitogen stimulation of peripheral blood T lymphocytes was performed by incubating cells with 1% phytohemagglutinin (PHA, Burroughs Welcome, Triangle Park, NC) for 48 hours. Interferon treatment of cells was performed by incubating cells with recombinant human γ-IFN (generously provided by Genentech, South San Francisco) at 500 U/mL for 72 hours. Cells from myeloid lines were induced to differentiate terminally in vitro by exposure to 1,25 dihydroxyvitamin D_3 [1,25(OH)$_2$D$_3$, 5×10^{-8} mol/L] (generous gift of M. Uskokovic, Hoffmann-La Roche, Nutley, NJ) for five days[40] or by exposure to 1.25% DMSO (Sigma) for five days.[41] Aliquots of the differentiated cells were incubated with γ-IFN for 72 hours. Viability of cells, assessed by trypan blue exclusion, was 65% to 90% after induction of terminal differentiation.

Prior studies showed that the Leu 10 antibody fails to react with HLA-DQ antigens on cells that are homozgous for the DR3 or DR7 HLA-DR allotypes.[31] The DR allotypes of cell lines used in this study were previously reported:[32] HL-60, DR 2,7; U-937, DR 4,6; Raji, DR3,6. The DR allotype of cell lines Me (DR 7,8) and KG-1 (MT2, associated with DR 3,5, W6) were determined by a microcytotoxicity assay.[42]

RESULTS

Immunofluorescent studies of expression of the HLA-DR and HLA-DQ antigens. Expression of HLA-DR and HLA-DQ antigens was determined by exposing cells to the murine monoclonal antibodies L243 and Leu 10, respectively, and measuring specific binding by indirect immunofluorescence. These monoclonal antibodies were previously used to study HLA-D antigen expression on lymphoid and myeloid cells.[7,9,15,16,31,32,43] Expression of HLA-DR and HLA-DQ antigens could be detected on cells from each of the human B and T lymphocyte cell lines (Fig 1, Table 2). More than 60% of each cell population expressed both antigens. The intensity of binding of the Leu 10 antibody was consistently less than that of the L243 antibody. Expression of both MHC class II antigens was most intense on T and B cells infected with the HTLV-I, in comparison to other lymphoid cells.

The myeloid cell populations expressed HLA-DR antigens to a variable extent (Fig 2, Table 3). Cell lines of immature phenotype including KG-1, KG-1a, and HEL[44,45,46] expressed the HLA-DR antigen on $>$75% of the cells. HLA-DR expression, however, was weak or absent on cells from relatively mature cell lines, such as HL-60 (promyelocytes)[47] or U-937 (monoblasts).[48] Exposure of HL-60 cells to 1,25(OH)$_2$D$_3$ induced morphological and cytochemical evidence of maturation to a macrophage-like phenotype in 90% of the cells, yet induced HLA-DR expression at low levels on only 20% to 40% of the cells (Fig 3).

Expression of the HLA-DQ antigens could not be detected on cells of the majority of the myeloid cell lines (Fig 4, Table 3). Only KG-1 and KG-1a cell lines, which manifest the phenotype of immature and very immature myeloblasts, respectively, expressed HLA-DQ antigens at low intensity on 12% of the cells. Peripheral blood monocytes and pulmonary

alveolar macrophages expressed HLA-DQ antigens on the surface of 25% to 30% of the cells. The HLA-DQ antigens, however, could not be detected on either HL-60 or U-937 cells induced to differentiate to macrophages in vitro by exposure to $1,25(OH)_2D_3$. Likewise, the HLA-DQ antigens could not be detected on peripheral blood granulocytes or on HL-60 cells induced to differentiate to metamyelocytes by exposure to 1.25% DMSO (Table 3).

Modulation of expression of HLA-DR and HLA-DQ by γ-IFN. Exposure to γ-IFN has been reported to increase expression of HLA-DR antigens on myeloid cells, including human fetal and adult peripheral blood monocytes[15-17,43] and cells from the myeloid lines HL-60, ML-1, and U-937.[15,48,49,50] We examined the effect of γ-IFN on expression of HLA-DR and HLA-DQ antigens by cells from a panel of myeloid cell lines that differed in their apparent degree of maturation. Exposure to γ-IFN increased expression of HLA-DR antigens on the surface of KG-1, ML-3, and HEL cells, and induced measurable expression on HL-60 cells (Fig 2). In some experiments, γ-IFN induced expression of HLA-DR on the surface of the U-937 cells. γ-IFN also caused a dramatic increase in expression of HLA-DR antigens on HL-60 and U-937 cells induced to differentiate to macrophagelike cells by exposure to $1,25(OH)_2D_3$ (Fig 3). Paradoxically, HL-60 cells exposed to DMSO expressed HLA-DR when subsequently incubated with γ-IFN. The HL-60 cells exposed to DMSO and γ-IFN morphologically resembled metamyelocytes and did not express nonspecific esterase, the cytochemical marker of macrophages. Peripheral blood granulocytes harvested from normal volunteers did not express HLA-DR antigens after a 48-hour exposure to 500 or 1,000 U/mL of γ-IFN in vitro (Table 3).

Similar to findings previously reported for HL-60 cells,[15] we found that γ-IFN exposure had disparate effects on HLA-DR and HLA-DQ antigen expression on cells of various myeloid lines. Exposure to γ-IFN increased HLA-DQ expression on KG-1 cells (Fig 5). HLA-DQ antigen expression could not be detected on other myeloid cell lines, however, either constitutively or after exposure to γ-IFN (Fig 5). Although HL-60 and U-937 cells exposed to $1,25(OH)_2D_3$ and γ-IFN differentiated in vitro to mature macrophagelike cells, the HLA-DQ antigen could not be detected on these cells.

Exposure of myeloid cells to either γ-IFN or other agents that induce differentiation in vitro increases the expression of Fc receptors.[51,52] Although murine IgG2a binds to the human Fc receptor,[53,54] the binding of L243 (IgG2a) to myeloid cells could not be attributed to Fc binding for several reasons. First, binding of L243 to the cells was significantly higher than binding of control IgG2a antibody to the same cell population in all cases. Binding of the control antibody was congruent with the background fluorescence (FITC antibody

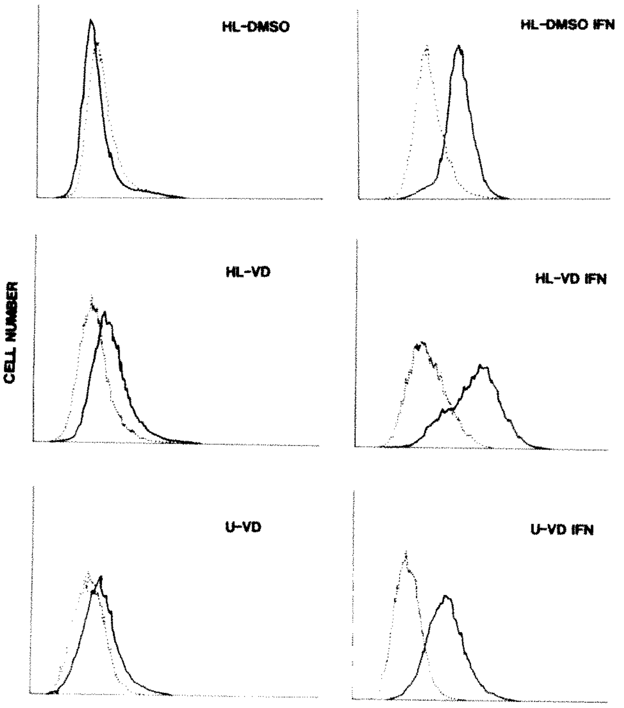

Fig 3. Cytofluorometric analysis of expression of the HLA-DR antigen on myeloid cells induced to differentiate in vitro. Cells from myeloid cell lines HL-60 and U-937 were induced to differentiate in vitro by exposure to either dimethyl sulfoxide (DMSO) or 1,25 dihydroxyvitamin D_3 (VD). Expression of HLA-DR antigen was measured as in Fig 2. Anti-HLA-DR (L243) antibody (—); control (murine monoclonal antibody, IgG2a) (· · ·). HL-DMSO and HL-VD, HL-60 cells induced to differentiate with DMSO or 1,25(OH)D_3, respectively; U-VD, U-937 cells induced to differentiate with 1,25(OH)D_3; IFN, cells exposed to recombinant γ-IFN 500 U/mL for 72 hours. Cell number on vertical axis is plotted as a function of log fluorescence intensity on the horizontal axis.

alone) in all cases except with the differentiated HL-60 cells, and, in these cells, the binding of L243 was substantially above that of the control antibody. Second, several cell types known to express Fc receptors failed to bind L243: granulocytes, U-937 cells, and DMSO-treated HL-60 cells.[55] Finally, the L243 antibody bound to the surface of differentiated HL-60 cells could not be displaced by subsequent incubation of cells with a 50-fold excess of human IgG (Fig 6).

HLA-DR pulse-chase studies. Almost all samples of lymphoid cells that we examined expressed more HLA-DR than did the myeloid samples. The difference was not secondary to cell surface area because both cell types were similar in size as determined by light microscopy (15 to 20 μm in diameter). The decreased expression of DR could be secondary to either decreased production or decreased survival of these proteins in the myeloid cells as compared with the lymphoid cells. Pulse-chase experiments were performed to determine the relative stability of HLA-DR proteins in and on Raji (lymphoid) cells and KG-1 (myeloid). Cells were pulsed with ^{35}S methionine for three hours, washed, and returned to culture in α medium with added unlabeled methionine for varying lengths of time. As shown in Fig 7 and Table 4, the relative stability of HLA-DR antigens was equivalent on Raji and KG-1 cells, with a half-life (t½) of <24 hours. The intensity of bands corresponding to the α (33 kd) and β (29 kd) chains of the DR antigen was identical in all samples, suggesting coordinated synthesis and expression of these subunits.[55]

Analysis of HLA-DR and HLA-DQ mRNA in myeloid and lymphoid cells. Previous studies using myeloid cells demonstrated that mRNA for HLA-DRα and β chains is expressed in myeloid cells that express HLA-DR antigen, but not in those cells that failed to express HLA-DR.[15] Induction of expression of HLA-DR antigens after exposure to γ-IFN was coincident with an accumulation of HLA-DR mRNA in HL-60 cells and in nonmyeloid cells.[15,56] We investigated the expression of mRNA for the HLA-DRα chain in myeloid and lymphoid cell lines by hybridization of Northern blots with a cDNA probe for the HLA-DR α chain (pDR α1) (Fig 8). The cells from each lymphoid line contained abundant HLA-DR α chain mRNA. This transcript was $\sim$1.4 kilobases (kb), as previously reported.[57,58] The cells of myeloid lines contained mRNA for HLA-DR α chain to a variable extent; no expression was detectable in HL-60 cells that also failed to express the HLA-DR antigen; mRNA levels were highest in KG-1 cells. The mRNA accumulation for DR crudely paralleled the level of antigen expression, with DR mRNA levels highest in HTLV-I-infected T and B lymphocytes (ME and ME-II).[59]

Accumulation of mRNA for HLA-DQ was studied by hybridization of Northern blots to a probe for the HLA-DQ α chain.[60,61] Under our hybridizing and washing conditions, the pDCH1 probe does not cross-hybridize with HLA-DR mRNA. Lymphoid cells expressed two mRNA bands, of 1.1 and 1.4 kb, which hybridized with the HLA-DQ α probe. mRNA for the HLA-DQ α chain could not be detected in the myeloid cell lines KG-1, ML-3, HEL, or HL-60, however. The lack of detectable HLA-DQ mRNA sequences in these myeloid cells probably does not represent a nonspecific degradation of mRNA because (a) the same mRNA pools were used for the HLA-DR and DQ mRNA experiments; (b) the RNA gels showed undegraded 18S and 28S bands; and (c) each filter was stripped of probe and rehybridized with a tubulin cDNA, and all samples had comparable amounts of mRNA for tubulin (data not shown).

DISCUSSION

We previously noted that HL-60 promyelocytic leukemia cells fail to express constitutively the MHC class II antigens but are stimulated to express HLA-DR antigens and mRNA on stimulation with γ-IFN.[15] In the present study, we showed that expression of MHC class II antigens and mRNA in human myeloid leukemia cell lines varies with stage of differentiation. The capacity of cells to express MHC class II antigens after exposure to γ-IFN is also related to the degree of maturation of the cells. Our data provide additional evidence for discoordinate regulation of expression of the HLA-DR and HLA-DQ antigens in human myeloid cells.

The HLA-DR antigens were expressed on all lymphoid lines that we studied, including T and B lymphocyte lines infected with HTLV-I as well as mitogen-stimulated periph-

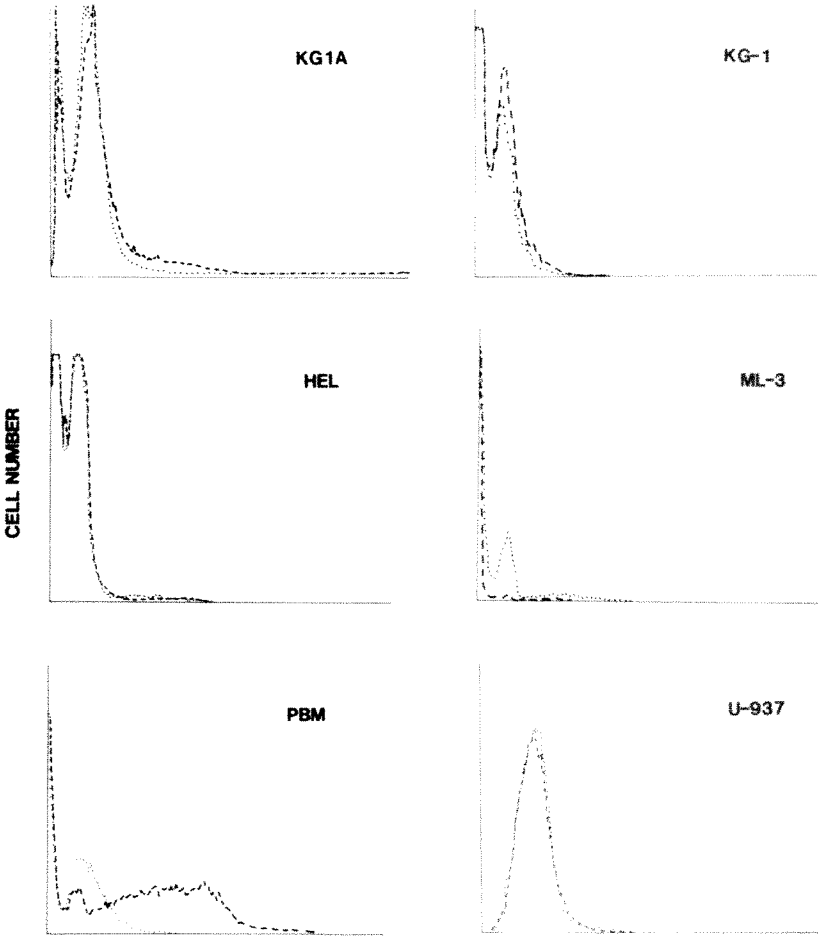

Fig 4. Cytofluorometric analysis of expression of the HLA-DQ antigens on myeloid cells. Myeloid cells from permanent lines or peripheral blood monocytes (PBMs) from normal volunteers were incubated serially with murine monoclonal antibody directed against the HLA-DQ antigen (Leu 10), and fluorescein-conjugated goat anti-mouse antibody (FITC anti-mouse); intensity of fluorescence was measured by flow cytometry. Cell number is plotted on a linear scale, and fluorescence intensity is plotted on a logarithmic scale. Cell number on vertical axis is plotted as a function of log fluorescence intensity on the horizontal axis. Cell lines KG-1, KG-1a, U-937, HEL, and ML-3 are described in the text. Anti-HLA-DQ (Leu 10) antibody (---); control (FITC goat anti-mouse antibody) (· · ·).

eral blood T lymphocytes. In contrast, HLA-DR antigens were expressed to a variable extent on cells from myeloid lines, with high levels of expression on myeloid cell lines with the phenotypes of either myeloblasts (KG-1 and KG-1a) or bipotent-erythroblasts/myeloblasts (HEL). Cell lines that manifested a greater degree of myeloid maturation, such as ML-3, HL-60, and U-937, expressed HLA-DR antigen at low or negligible levels. Although peripheral blood monocytes and pulmonary alveolar macrophages expressed HLA-DR antigens at high levels on 85% to 100% of the cells, terminal differentiation of HL-60 and U-937 to macrophagelike cells in vitro induced expression of HLA-DR antigen at a low intensity on only 25% to 50% of cells.

The HLA-DQ antigens were detectable on all lymphoid cells with the exception of peripheral blood T lymphocytes. The intensity of binding of the Leu 10 antibody was less than that of L243 on each cell line. This may indicate a lower level of expression of HLA-DQ antigens on these cells. Although the antibodies are of different isotype and may differ in affinity for their respective antigens, the antibodies were used in saturating concentrations. Under these conditions, the level of antibody binding is proportional to antigen expression.[8,62] Similarly, the FITC anti-mouse antibody was present at saturating levels. Other investigators have reported that antigen density of HLA-DQ was apparently less than that of HLA-DR on human monocytes.[8]

The KG-1 and KG-1a myeloblast cells weakly expressed HLA-DQ antigens on a low percentage of cells. The HLA-DQ antigens could not be detected on other myeloid cell lines of more differentiated phenotype. HLA-DQ expression was measurable on 25% to 30% of peripheral blood monocytes and pulmonary alveolar macrophages, however. Our inability to detect DQ expression on myeloid cell lines cannot be explained by the allotype specificity of the Leu 10 antibody because several of the myeloid cell lines have been typed for HLA-DR and are not homozygous for DR3 or DR7. Conversely, the binding of Leu 10 to lymphoid cells probably cannot be attributed to artifactual binding to cross-reactive non-DQ antigens. In serial immunoprecipitation studies of lymphoblastoid cells, Leu 10 specifically immunoprecipitated HLA-DQ polypeptide chains.[31] Our results provide further evidence that HLA-DR antigen expression may be regulated independently of that of HLA-DQ in myeloid cells. Several investigative groups have reported that monocytes from peripheral blood express HLA-DQ antigens at lower levels than HLA-DR, and that 50% to 75% of monocytes are negative for HLA-DQ by immunofluorescence.[7,8,16,17] Discoordinate expression of DR and DQ antigens has also been described in studies of hematopoietic progenitor cells and leukemic blast cells. Granulocyte-macrophage progenitor cells (GM-CFC) from normal human bone marrow expressed HLA-DR in studies using FACS and complement-

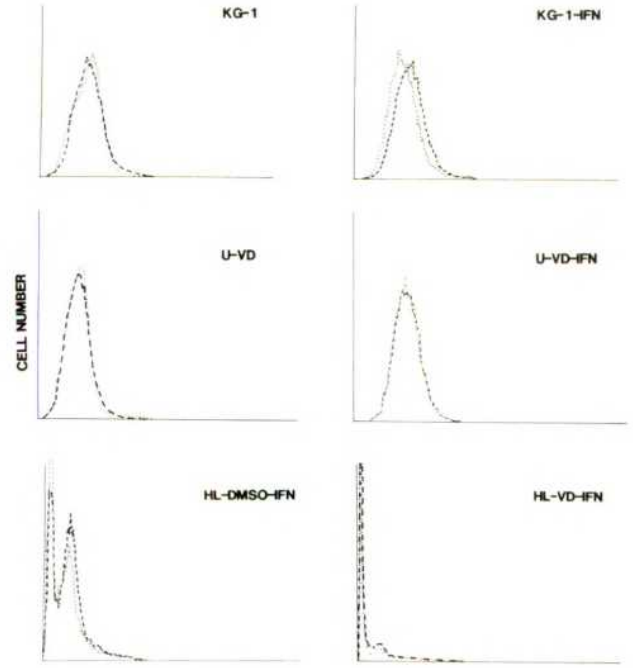

Fig 5. Cytofluorometric analysis of expression of the HLA-DQ antigens on myeloid cells: effect of γ-interferon (γ-IFN). Myeloid cells from lines were cultured in α medium for 72 hours with and without γ-IFN. Expression of HLA-DQ antigen was determined as described in the legend for Fig 5. Anti-HLA-DQ (leu 10) antibody (---); control (FITC goat anti-mouse antibody) (· · ·). IFN, cells exposed to recombinant γ-IFN 500 U/mL for 72 hours. Cell number on vertical axis is plotted as a function of log fluorescence intensity on the horizontal axis.

mediated cytotoxicity.[9] When marrow cells were incubated with antibody directed against HLA-DQ and sorted by FACS, however, GM-CFC were found only in the HLA-DQ–negative fraction.[9] Two investigative groups noted that expression of HLA-DR antigen could be measured on most leukemic blast cells, whereas HLA-DQ antigen was limited to a subset of the leukemic cells.[63,64]

The level of expression of the HLA-DR and HLA-DQ antigens is probably in part regulated at a pretranslational level. Low or undetectable levels of mRNA for the HLA-DR α and HLA-DQ α chain were noted in cells that expressed negligible levels of the corresponding antigens. The level of HLA-DRα mRNA expression was markedly lower in myeloid cells as compared with lymphoid cells, yet levels of HLA-DR antigen expression varied to a much smaller extent. This discrepancy could not be attributed to degradation of the myeloid RNA, nor did it represent decreased stability of the HLA-DR antigen on myeloid cells. The turnover of HLA-DR antigen after metabolic labeling was similar in myeloid and lymphoid cells. Prior studies using melanoma cell lines noted a discrepancy between the level of expression of mRNA for the HLA-DR antigens and surface membrane expression of the HLA-DR antigens.[56] Messenger RNA "run-on" and stability experiments will help to elucidate this discrepancy.

The level of binding of the cDNA probes for HLA-DR to RNA blots should provide an accurate indication of the level

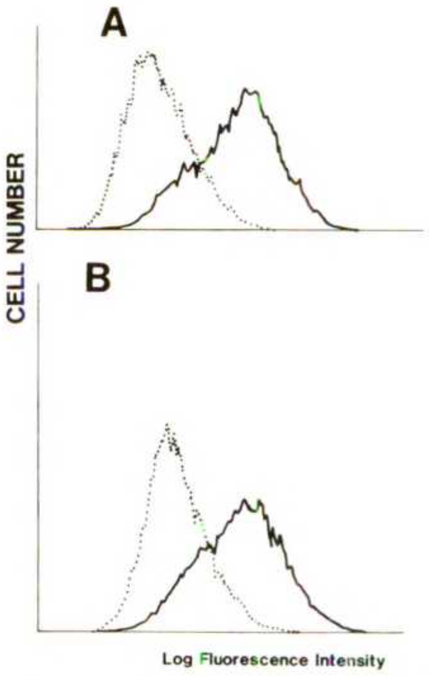

Fig 6. Cytofluorometric analysis of expression of the HLA-DR antigen on myeloid cells: effect of Fc receptor blockade with human IgG. HL-60 cells were induced to express HLA-DR antigen by incubation with dimethylsulfoxide (DMSO) and γ-IFN. Cells were incubated with (A) anti-HLA-DR antibody (L243, 300 nmol/L), or (B) with L-243 (300 nmol/L) followed by human IgG [15μmol/L], and HLA-DR expression was measured by flow cytometry after incubation of cells with FITC anti-mouse antibody. Cell number is plotted on a linear scale, and fluorescence intensity is plotted on a logarithmic scale. Anti-HLA-DR (L243) antibody (—); control [murine monoclonal antibody (IgG2a)] (· · ·).

of expression of mRNA for the HLA-DR antigens. The cDNA probes were derived from nonpolymorphic regions of the RNA transcript encoding the DR α chain, and react with α chain RNA from cells of all DR types.[25,26,57] Measurement of DR α chain RNA is also probably an accurate reflection of

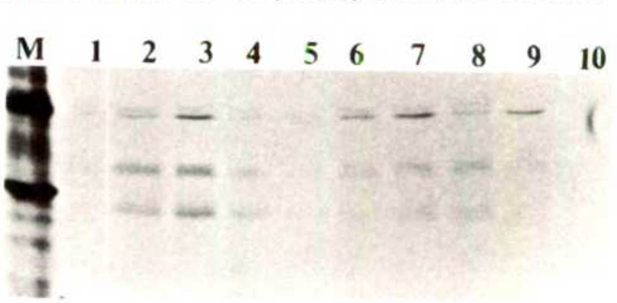

Fig 7. Turnover of proteins for HLA-DR antigen on lymphoid and myeloid cells. Lymphoid (Raji) cells (lanes 1 through 5) and myeloid (KG-1) cells (lanes 6 through 10) were incubated with ^{35}S methionine for three hours, washed, and returned to culture with unlabeled methionine (cold chase). Aliquots were removed after being labeled with ^{35}S-methionine (lanes 1 and 6), and after 3 hours (lanes 2 and 7), 6 hours (lanes 3 and 8), 24 hours (lanes 4 and 9), and 48 hours (lanes 5 and 10) of the chase period. Cells were lysed, and HLA-DR antigen proteins were immunoprecipitated and analyzed as described in the text. Lane M, mol wt standards, 30 kd and 46 kd.

Table 4. Turnover of HLA-DR Antigen Proteins on Lymphoid and Myeloid Cells

	Density of Hybridization Grains on Film	
Duration of Chase Period (h)	Raji Cells	KG-1 Cells
0	140	150
3	1,620	1,170
6	2,350	800
24	780	280
48	70	50

Lymphoid (Raji) and myeloid (KG-1) cells were labeled with ^{35}S methionine and returned to culture with unlabeled methionine (cold-chase) as described in the legend for Fig 7. HLA-DR proteins in cell lysates were analyzed by immunoprecipitation, sodium dodecyl sulfate-polyacrylamide gel electrophoresis and autoradiography at −70°C, using preflashed Kodak XAR film and an intensifying screen. The density of silver grains corresponding to protein bands of 29 kd and 33 kd was quantitated with a laser densitometer (Joyce-Leoble) and expressed in arbitrary units.

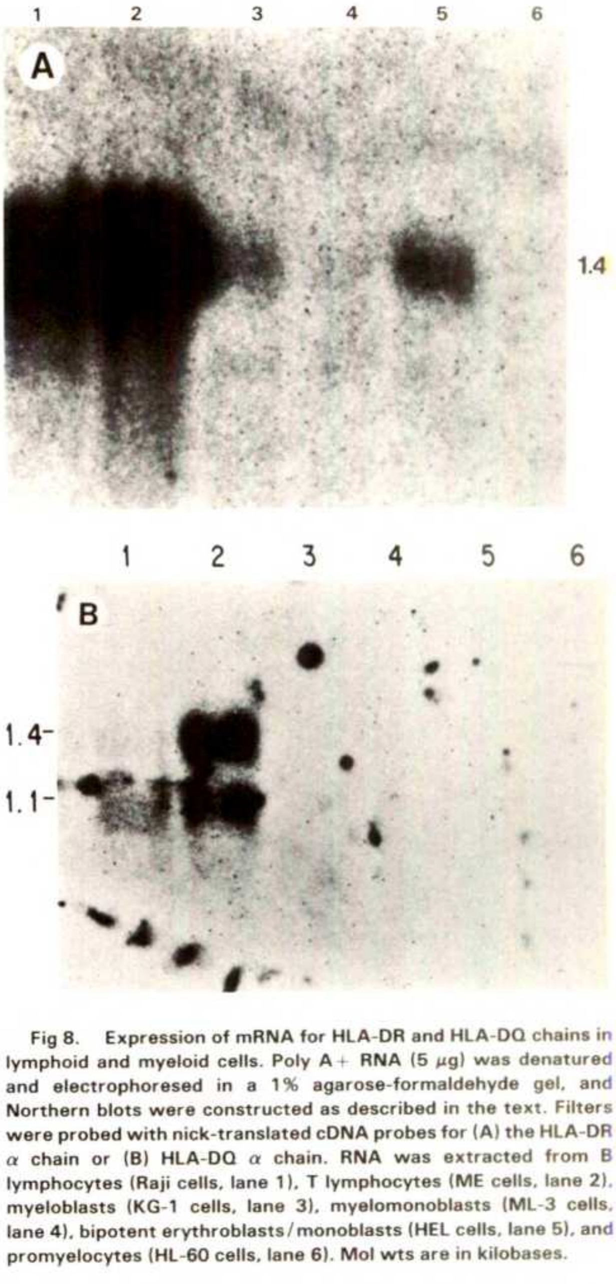

Fig 8. Expression of mRNA for HLA-DR and HLA-DQ chains in lymphoid and myeloid cells. Poly A+ RNA (5 μg) was denatured and electrophoresed in a 1% agarose-formaldehyde gel, and Northern blots were constructed as described in the text. Filters were probed with nick-translated cDNA probes for (A) the HLA-DR α chain or (B) HLA-DQ α chain. RNA was extracted from B lymphocytes (Raji cells, lane 1), T lymphocytes (ME cells, lane 2), myeloblasts (KG-1 cells, lane 3), myelomonoblasts (ML-3 cells, lane 4), bipotent erythroblasts/monoblasts (HEL cells, lane 5), and promyelocytes (HL-60 cells, lane 6). Mol wts are in kilobases.

expression of mRNA for the DR β chain, because previous studies demonstrated coordinate expression of α and β chain mRNA and polypeptides in human cells.[15,55,58,65] The pattern of binding to the DQ α probe, pDCH1, is less predictable. At least two genes homologous to DQ α have been identified in the human genome.[61,66] In addition, the expression of the known alleles of DQ are in linkage disequilibrium with specific DR allotypes. We used a cDNA probe homologous to the gene for the α chain of the DC 4 allele, a DC gene that is in linkage disequilibrium with DR allotypes DR4, DR7, and DR9. This probe reacts with RNA from Raji cells (DR3, DR6).[66] In our study, the DC α probe reacted with RNA from Raji cells and ME cells (DR7, DR8). Because the HL-60 cells express DR2 and DR7 and therefore should express DQ4,[32,60,61] the failure to detect DQ α RNA from HL-60 cells probably cannot be attributed to the allotype specificity of the DQ α probe. Two transcripts that hybridized with the PDCH1 probe were noted in Raji cells and ME cells. This pattern of expression was previously noted in RNA from Raji cells[66] and in human endothelial cells[58] and was due to alternative RNA splicing patterns in the 3′ untranslated region of the mature DC α transcript.

The relatively higher level of HLA-DR antigen expression in lymphoid cells as compared with myeloid cells could not be accounted for by changes in the stability of the HLA-DR antigen in these cells. We noted a t½ of <24 hours, similar to the t½ of the I-A antigen on murine macrophages cultured in vitro.[67,68] In contrast, human endothelial cells and dermal fibroblasts continue to express HLA-DR antigens at high levels for >96 hours after withdrawal of γ-IFN.[58] The differences in turnover rate between hematopoietic cells and dermal fibroblasts may reflect the growth rate of the cells, the culture conditions, or tissue-specific variation in antigen stability.

We studied the effect of γ-IFN on HLA-DR and HLA-DQ expression because this lymphokine is known to activate myeloid cells in the immune response. Secretion of γ-IFN by T lymphocytes stimulates parameters of myeloid function, such as interleukin-1 (IL1) synthesis, which are essential for antigen presentation.[13,14] γ-IFN also restores expression of MHC class II antigens on human monocytes cultured in vitro, induces expression of HLA-DR antigens on HL-60 cells, and induces differentiation of myeloid cell lines toward a monocytic phenotype.[7,15-17,69,70] We demonstrated that γ-IFN increases expression of HLA-DR antigens on the surface of several myeloid cell lines. This response to γ-IFN was heightened when HL-60 cells were induced to differentiate terminally with 1,25(OH)$_2$D$_3$. Similarly, U-937 cells, which expressed low to unmeasurable levels of HLA-DR antigen after exposure to γ-IFN alone, were induced to express DR antigens by sequential treatment with 1,25(OH)$_2$D$_3$ and γ-IFN. Other investigators showed that HLA-DR expression could be induced by γ-IFN in U-937 cells pretreated with 5-azacytidine.[49]

HL-60 cells induced to differentiate with DMSO expressed DR antigens after subsequent exposure to γ-IFN. The intensity of expression and the percentage of cells that expressed DR was markedly higher than that seen after exposure of uninduced HL-60 promyelocytes to γ-IFN. Exposure of HL-60 to DMSO alone induced maturation to metamyelocytes as determined by morphology but failed to induce expression of HLA-DR antigens. Because DMSO induces HL-60 cells to express many of the phenotypic and cytochemical characteristics of granulocytes, we examined the expression of HLA-DR on normal human granulocytes exposed to γ-IFN in vitro and found that these cells had undetectable HLA-DR expression. This result suggests that cells from cell lines induced to differentiate in vitro do not bear a strict resemblance to their terminally differentiated counterparts in vivo.[71] In previous reports, DMSO-treated HL-60 cells functioned as accessory cells in T cell stimulation despite their absence of HLA-DR antigen expression.[14] In contrast, HL-60 promyelocytes were not able to function as accessory cells.

The HLA-DQ expression could not be detected on myeloid cell lines after γ-IFN exposure. The only exception to this pattern occurred in KG-1 cells, in which γ-IFN led to a slight, but consistent, increase in the expression of HLA-DQ antigen. In our earlier study, we noted that HL-60 cells did not express HLA-DQ antigens or mRNA after exposure to γ-IFN.[15] Recently, Nunez and colleagues reported that treatment with T cell-conditioned medium failed to induce expression of HLA-DQ in HLA-DQ(−) monocytes.[17] Gonwa and Stobo noted that γ-IFN restored the expression of DR α and DQ α on monocytes maintained in culture. They did not determine whether γ-IFN induced DQ expression de novo or served to restore expression of DQ α on cells that had previously been DQ positive.[7] Basham and Merigan also reported that γ-IFN induced expression of DR and DQ by monocytes, but they noted increased expression of DQ on monocytes maintained in culture, independent of IFN.[16] Collins and co-workers[58] reported that γ-IFN induced expression of HLA-DQ, DR, SB antigens, and mRNAs in human vascular endothelial cells and in dermal fibroblasts in vitro.

Three conclusions are suggested by these studies: (a) The expression of HLA-DQ and HLA-DR may be discoordinate in myeloid cell lines and in freshly isolated human cells of myeloid lineage; (b) exposure of monocytes to γ-IFN increases expression of both HLA-DR and HLA-DQ on the cells, but does not cause most HLA-DQ(−) cells to manifest the DQ antigen; and (c) expression of DR and DQ antigens is labile and may vary with culture conditions. Our inability to detect DQ antigens and mRNA from cells of most myeloid lines probably cannot be ascribed to the reagents used to measure expression of antigen and mRNA, for the reasons noted above. Failure to induce DQ expression may be a function of culture conditions. Both Gonwa and Stobo[7] and Basham and Merigan[16] cultured cells in autologous serum; we used fetal calf serum. The type of serum used to culture murine and human myeloid cells can significantly influence functional properties and expression of MHC class II antigens.[12,72,73] In our study, myeloid cell lines induced to differentiate to macrophagelike cells in vitro failed to express DQ antigens before or after exposure to γ-IFN, in contrast to normal monocytes and macrophages. This finding suggests that factors in addition to γ-IFN and differentiation state of the cell may regulate DQ expression.

The pattern of expression of human MHC class II antigens by myeloid cells appears to be different from the expression of MHC class II antigens by murine myeloid cells. Most murine macrophages express I-A–encoded antigens, which are structural homologues to the human HLA-DQ antigens. Only a minor population of murine macrophages display I-E–encoded antigens (DR homologues).[67] Murine γ-IFN induces expression of I-A mRNA and antigen on murine macrophages,[74,75] induces expression of I-A mRNA in cells of the murine macrophage line P388D,[76] and induces expression of I-A and I-E antigens on another murine myeloid cell line, WEHI-3.[77]

Mutations in N-*ras* Predominate in Acute Myeloid Leukemia

By Johannes L. Bos, Matty Verlaan-de Vries, Alex J. van der Eb, Johannes W.G. Janssen,
Ruud Delwel, Bob Löwenberg, and Loes P. Colly

Using synthetic oligomers we investigated fresh samples of acute myeloid leukemia (AML) for the presence of mutated *ras* oncogenes. Our original results showed that five of eight samples contained a mutation in codon 13 of the N-*ras* gene. In a subsequent study involving 37 samples, we found only one N-*ras*-13 mutation, and, in addition, mutations in codon 61 of the N-*ras* gene in four cases and a mutation in codon 12 of the Ki-*ras* gene in two cases. Amplification of *ras* genes was not observed. We conclude that in ~20% to 25% of AML cases, a mutated *ras* oncogene is present, predominantly the N-*ras* gene. The occurrence of mutations does not correlate with the cytological features of the leukemia.

THE HUMAN *ras* family consists of three members, the Ha-*ras*, Ki-*ras*, and N-*ras* genes. They encode homologous proteins of 21 kd, whose cellular location is at the inner surface of the plasma membrane.[1,2] The 21-kd Ha-*ras* protein binds guanine nucleotides and exhibits GTPase activity.[3,4] In this respect, the protein resembles the "G proteins," which are known to be involved in the transduction of receptor-mediated external signals into the cell. A recent study showed that cells injected with *ras*-specific monoclonal antibodies, which presumably inactivate the Ha-*ras* protein, were incapable of entering S-phase of the cell cycle. This suggests that the Ha-*ras* protein plays an essential role in the cell cycle.[5]

In 10% to 20% of the human tumors or tumor-derived cell lines tested, one of the *ras* genes is activated. These activated genes differ from their normal counterparts by their ability to convert the mouse NIH 3T3 cell line into tumorigenic cells.[6] This difference is caused by single point mutations in the coding sequence of the *ras* genes. These mutations occur either in codon 12 or 61 of one of the *ras* genes[7] or in codon 13 of the N-*ras* gene.[8] At least in one case, these mutations affected the GTPase activity of the protein product.[3,4] The current hypothesis is that normal *ras* proteins bind GTP in response to some receptor-mediated signal and, in doing so, transduce the signal further into the cell. Signal transmission would terminate with the intrinsic GTPase activity converting GTP to GDP. In mutated *ras* proteins, the GTPase activity is reduced, resulting in prolonged binding of GTP and hence prolonged activation. In this way, the proper functioning of the signaling pathway in which *ras* proteins are involved is disturbed. Because the *ras* proteins most likely play an important role in cell cycle control, changes in this activity conceivably contribute significantly toward uncontrolled growth, as occurs in tumor cells. Results of Land and colleagues[9] and Ruley,[10] however, showed that additional changes are required in the process of carcinogenesis. These authors established with transfection experiments that primary cell cultures cannot be transformed by an activated Ha-*ras* gene alone, but that an additional "activated" oncogene is required. One of these oncogenes is the c-*myc* gene, which also plays a role in the control of the cell cycle.[11]

To assess the significance of *ras* gene mutations in human tumorigenesis, we are investigating the occurrence of these mutations in fresh samples from human malignancies. For this purpose, we set up a rapid screening assay using synthetic oligonucleotide probes.[8,12,13] In this report, we describe the analysis of 37 samples of acute myeloid leukemia (AML). As reported earlier, five of eight samples analyzed previously contained an N-*ras* mutation in codon 13.[8] In the present 37 samples, we found 7 *ras* gene mutations, of which only one is in codon 13 of the N-*ras* gene.

MATERIALS AND METHODS

Materials. Samples of leukemic cells were taken from peripheral blood or bone marrow and purified over Ficoll gradients. The cells were stored either in liquid nitrogen or in 70% ethanol at 4 °C.

DNA isolation. DNA was isolated as described by Davis and colleagues.[29] Cells were lysed in 500 μL of 0.5% sodium dodecyl sulfate (SDS), 0.1 mol/L of NaCl, 50 mmol/L of Tris-Cl pH 8.0, and 1 mmol/L of EDTA, and incubated 30 minutes at 65 °C with 100 μg/mL of proteinase K; 75 μL of 8 mol/L of potassium acetate was added, and the incubation was allowed to proceed for 15 minutes at 0 °C. The precipitate generated was spun down in an Eppendorf centrifuge, and the supernatant was extracted with 750 μL of chloroform. Subsequently, the DNA was precipitated with ethanol and dissolved in 150 to 300 μL of 10 mmol/L of Tris-Cl pH 8.0 and 0.1 mmol/L of EDTA.

Synthetic oligonucleotide probes. The oligomers were synthesized by G. Veeneman and J. H. van Boom (Organic Chemistry Department, University of Leiden) by the solid-phase triester method. ^{32}P Labeling of the oligomers was obtained by a primer extension reaction using an 8-mer primer as described.[12]

Oligomer hybridizations. DNA was digested with suitable restriction enzymes under the conditions suggested by the supplier (*Pst*I to detect mutations in the N-*ras* gene and the Ki-*ras* gene, *Sst*I for mutations in the Ha-*ras* gene) and fractionated by electrophoresis in 0.5% agarose. The gel was treated as described[12] to denature the DNA in situ and to immobilize the DNA by drying the gel. The dried gels were incubated with the different oligomer probes in 5 × SSPE (1 × SSPE = 10 mmol/L of sodium phosphate pH 7.0,

0.18 NaCl, and 1 mmol/L of EDTA), 1% SDS, and 100 μg/mL of denaturated salmon sperm DNA for 16 hours at the following temperatures: oligomer probes from the N12 and K12 group (Table 1) at 53 °C, oligomers of the N61 and K61 group at 50 °C, oligomers of the H12 group at 60 °C, and oligomers of the H61 group at 55 °C. The gels were washed at 2 × SSPE and 1% SDS at room temperature and incubated at 5 × SSPE, 1% SDS for 10 minutes at the following temperatures: gels hybridized with N12 and K12 oligomer probes at 63 °C, with N61 and K61 probes at 59 °C, with H12 probes at 73 °C, and with H61 probes at 67 °C. All individuals have given consent to donate bone marrow and blood.

RESULTS

To analyze mutations present in codons 12, 13, and 61 of the N-*ras* gene and in codons 12 and 61 of the Ki-*ras* and Ha-*ras* genes, we used synthetic 20-mer oligonucleotide probes (Table 1). With these probes, we are able to detect all possible single base pair substitutions in these codons, because a fully matched hybrid between the oligomers and genomic DNA is thermally more stable than a single base pair-mismatched hybrid. Our analysis was conducted as follows: AML DNA was digested with a restriction enzyme (*Pst*I or *Sst*I) and electrophoresed through agarose to separate the restriction fragments. This DNA was hybridized to various ^{32}P-labeled oligomers probes complementary to the sequences that might contain a mutation. The hybridization conditions allow only hybridization of perfectly complementary oligomers and not of those with one or more mismatches. For instance, the N12 oligomer probe (Table 1) is complementary to the sequence around codon 12 of the N-*ras* gene. Under the experimental conditions, this probe will hybridize to the N-*ras* gene only when no mutations are present in codon 12 or codon 13. To detect mutations in the *ras* genes, we prepared a set of probes in which all mutations are represented that can occur in codon 12 and 61 of the Ha-*ras*, Ki-*ras*, and N-*ras* genes and in codon 13 of the N-*ras* gene. Only these codons are affected in naturally occurring tumors. To reduce the number of hybridizations, we used pooled mutation-specific probes. Each pool contains the oligomers homologous to all possible non-silent mutations of one particular base pair. For instance, the N61-p2 oligomer probe (Table 1) consists of three different oligomers homologous to the possible mutations at the second position (p2) of codon 61 of the N-*ras* gene (N61). Figure 1 shows six examples (a through f) of our hybridization analysis. In each example, three different AML DNAs were hybridized to codon 12 probes for either the N-*ras* gene (a through d) or the Ki-*ras* gene (e, f) (lefthand column), and to codon 61 probes for either the N-*ras* gene or the Ki-*ras* gene (middle column). The righthand column represents hybridization with various pools of mutation-specific oligomers that specify the mutation present in the AML DNAs. Among 37 cases of untreated AML, we found seven samples with a *ras* gene mutation (Fig 1): three at position 2 and one at position 3 of codon 61 of the N-*ras* gene, one at position 2 of codon 13 of the N-*ras* gene, and two at position 2 of codon 12 of the Ki-*ras* gene. No mutations were found in codons 12 and 61 of the Ha-*ras* gene or in codon 61 of the Ki-*ras* gene. Subsequently, we also determined the exact base pair change in these samples using individual oligomer probes. The results are shown in Table 2 together with those obtained for the eight AML samples analyzed previously.[8] From them, we conclude that in AML the N-*ras* gene is the preferentially activated member of the *ras* gene family.

Table 1. Sequences of the 20-mer Probes of the N-*ras*, Ki-*ras*, and Ha-*ras* gene

Oligomer	Sequence		Strand*
N12	GGAGCAggtGGTGTTGGGAA		y

H61	TACTCCTCctgGCCGGCGGT		n
H61-p1	--------ctn---------	n = C,A,T	n
H61-p2	--------cng---------	n = C,A,G	n
H61-p2	--------ntg---------	n = A,G,	n

Indicated are the oligomers complementary to the normal sequence. Mutation-specific oligomers are derived from these normal oligomers. For instance, N61-p2 is a mixture of oligomers identical to the wt-oligomer except for the normal G-residue at position two of the codon 61. At this position, A, C, and T residues are present in the three oligomers of this mixture.

*Sequence complementary to the coding (n) or noncoding (y) strand.

A *ras* gene can be activated alternatively by amplification of the gene.[15-17] To identify possible amplifications, we hybridized the DNAs with oligomer probes complementary to normal *ras* sequences (Table 1) and compared the hybridization intensities of the wt-probes for the three *ras* oncogenes. In no case was amplification of any of the *ras* genes found (not shown). In all samples in which a mutation was detected, however, both a normal allele and a mutant allele existed. That our samples were consistent for >90% of tumor cells (as determined by light microscopy) suggests that the *ras* gene mutation is heterozygous. Alternatively, the *ras* gene mutation occurs in only a subpopulation of the leukemia cells.

Table 2 includes the classification of the AMLs that contain a *ras* gene mutation. We have not yet found any correlation between the presence of a *ras* gene mutation and cytological features of the leukemia.

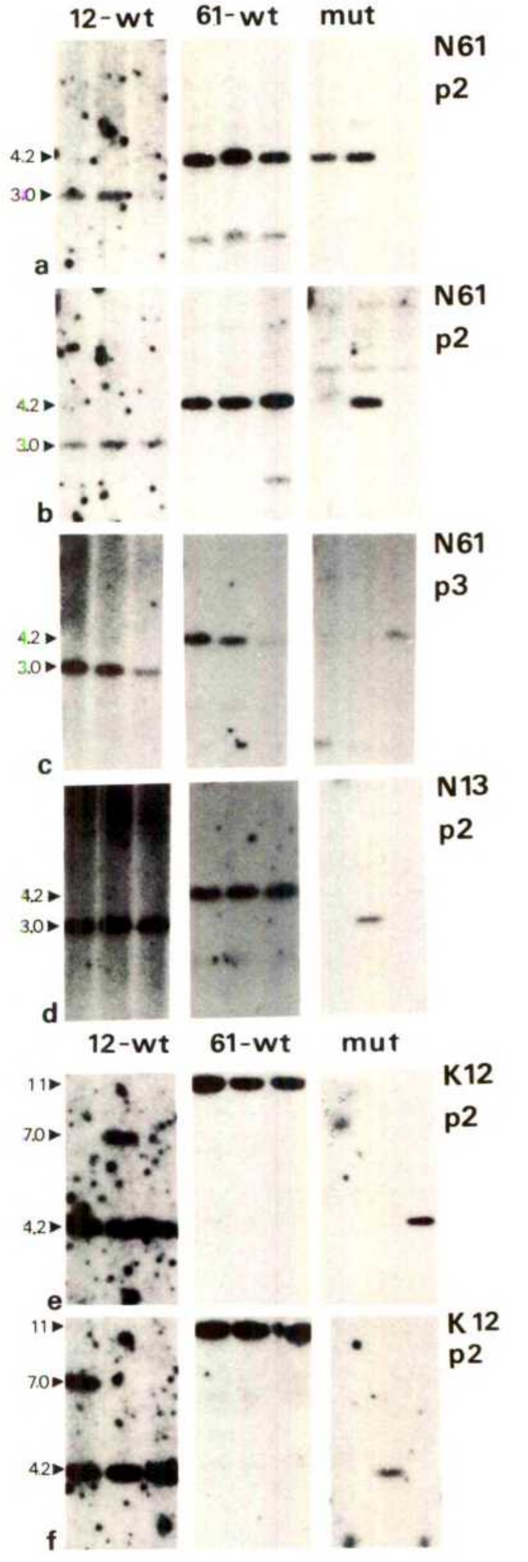

Fig 1. Hybridization of synthetic oligomers to genomic DNA of various samples of acute myeloid leukemia (AML). The DNA was digested with *Pst*I, electrophoresed through agarose, and hybridized in situ to oligomer probes (described in Materials and Methods section): (a) hybridization of three different AML DNAs with the N12-wt oligomer probe (lefthand panel), with the N61-wt oligomer probe (middle panel) and with the mutation-specific oligomer probes N61-p2 (righthand panel); (b through d) as in a, but now in each case three other AML DNAs hybridized with the N12-wt probe, the N61 wt probe, and the mutation-specific probes N61-p2, (b), N61-p3 (c), and N13-p2 (d); (e, f) as in a through d but now Ki-*ras*-specific probes were used: K12-wt (lefthand panel), K61-wt (middle panel), and K12-p2 (righthand panel). The length of the hybridizing fragments is expressed in kilobase pairs (kb). N12 probes hybridize to 3.0-kb *Pst*I fragments, N61 probes to 4.2 kb *Pst*I fragments, and K12 and K61 probes to 4.2-kb and 11-kb *Pst*I fragments, respectively. The 7.0-kb band that hybridizes with the K12-wt probe is a *Pst*I restriction fragment-length polymorphism of the Ki-*ras* gene.

Table 2. *Ras* Gene Mutations in Acute Myeloid Leukemia

	AML	FAB Classification	Mutation

AML, acute myeloid leukemia; FAB, French-American-British.

DISCUSSION

Our results and those of others[7] show that *ras* gene mutations occur relatively infrequently, ranging from 5% in mammary tumors[18] and urinary tract tumors[19] to ~25% in AML. In all cases studied, the mutation is specific for the tumor cells and not present in the normal cells of the same individual. The mutations seem to occur randomly among the subtypes of particular malignancies. This may indicate that *ras* gene mutations do not contribute to the genesis of a tumor but arise randomly due to genetic instability of the malignant cells and/or the presence of mutational hot spots at position 12 and 61. In this case, *ras* mutations would be neither essential nor important. Obviously, the latter idea is unlikely, since mutated *ras* oncogenes contribute to the process of carcinogenesis in DNA transfection experiments.[7] A strong indication in support of the importance of *ras*-gene activation in tumorigenesis is the observation that in rats nearly all mammary tumors induced by a single injection of methylnitrosamine contain activated Ha-*ras* genes with a mutation at the same position.[20] An important role of *ras* gene activation in carcinogenesis is further indicated by other studies on chemically induced tumors.[21,22]

A puzzling result is that 5 of the 8 AMLs initially analyzed contained a mutation in codon 13 of the N-*ras* gene,[8] whereas of 37 samples tested later only 1 contained a mutation in that codon, although 6 additional mutations were found at other positions. The high frequency of *ras* mutations in the first eight samples may be explained by the fact that they were analyzed for their ability to oncogenically transform NIH-3T3 cells, as measured by tumor formation in athymic nude mice. This biological assay may be more sensitive than our procedure, especially when only a fraction of the cells in the tumor sample contain a mutation in one of their *ras* genes. This did not seem the case for the first five N-*ras*-13 mutations, however, since they were readily detected by the oligonucleotide probes[8] in the original tumor material, suggesting that the bias for N-*ras*-13 mutations probably is not due to an insufficient sensitivity of our procedure. Moreover, the new *Hph*I site indicative for one of the mutations in the N-*ras*-13 codon (GAT:asp)[8] was not present in other samples of AML (not shown). Because in both studies the samples of AML were collected randomly, the high frequency of N-*ras*-13 mutations in our original study seems to be fortuitous.

Our results show that in AML the preferentially mutated *ras* gene is N-*ras*. This activated oncogene has also been detected in three other samples of AML cells freshly isolated from patients[23-25] and in the AML-cell lines HL60,[12,24] Rc-2a, and KG1.[26] In addition, in acute lymphoid leukemia (ALL) cells, we also found N-*ras* mutations (two N-*ras*-12 mutations in 19 samples analyzed).[27] Probably, N-*ras*, as opposed to the other *ras* genes, plays a predominant role in the control of proliferation and differentiation of cells in the hematopoietic lineage. Alternatively, the preferential activation of N-*ras* may be due to the exposure or sensitivity of myeloid cells to a particular mutagen.

AML is a malignant disorder in which an early progenitor cell is transformed at some point in its differentiation from pluripotent stem cell to committed granulocyte/monocyte colony-forming cells (GM-CFU).[27] The ability of these cells to proliferate and mature is impaired and is manifested in the accumulation of immature blast cells. The differentiation level of the immature cell that accumulates is the basis of the current (French-American-British) classification of AML (M1 through M6). Nonrandom chromosomal aberrations correlate with certain stages of the morphological classification.[28] This suggests that these chromosomal abnormalities affect functions that are responsible for specific steps in differentiation, such as the production of factors responsible for normal myeloid differentiation or cell surface receptors for such factors. Activation of N-*ras*, however, is apparent among different classes of AML, suggesting that N-*ras* does not play a stage-specific role during differentiation. An attractive possibility is that in leukemogenesis an activated N-*ras* gene cooperates with a defect in the maturation pathway, thus providing the leukemic stem cell with the potential of self-renewal, especially when the leukemia arises from a more differentiated, committed stem cell with limited proliferative potential.

It would be interesting to investigate whether N-*ras* activation already occurs at the level of the pluripotent stem cell and is thus present in other nonleukemic, hematopoietic cells as well, or is restricted only to the leukemic cells or their immediate progenitor.

Improved Results of Treatment of Adult Acute Lymphoblastic Leukemia

By Charles A. Linker, Lee J. Levitt, Margaret O'Donnell, Curt A. Ries, Michael P. Link,
Stephen J. Forman, and Mark J. Farbstein

We designed a treatment program to improve the outcome for adults with acute lymphoblastic leukemia (ALL). Treatment included a remission-induction phase followed by intensive alternating cycles of non-cross-resistant chemotherapy and prolonged oral maintenance therapy. Eighty-one consecutive previously untreated patients were entered on this study. Ninety-four percent of patients entered complete remission. A Kaplan-Meier analysis predicts that 53% ± 9% (SEM) of patients in remission will remain free of disease at 3 years. Neither age, sex, WBC count, nor immunophenotype had a significant effect on remission duration. This program of intensive cyclical chemotherapy has improved the disease-free survival of patients with adult ALL.

© 1987 by Grune & Stratton, Inc.

PROGRESS in the treatment of adult acute lymphoblastic leukemia (ALL) has lagged behind that in the treatment of ALL in children. Using relatively nontoxic remission-induction and continuation therapy, 90% of children will enter complete remission, and 50% to 60% of these remissions will be durable.[1,2] Thus, approximately half of the patients with childhood ALL will be cured of their disease. Adults treated with similar programs, however, have only a 50% complete remission rate, and there are few long-term survivors.[3]

This clinical study was initiated with the hope that a different approach to the treatment of adult ALL would yield improved results. Several factors led us to believe that treatment results could be improved. First, reports of ongoing studies in adult ALL suggested that intensified therapy would increase both the complete remission rate and remission duration.[4,5] Second, use of repeated courses of high doses of alternating non–cross-resistant agents produced improved results in the treatment of acute myelogenous leukemia in both children and adults.[6] Third, encouraging reports on the use of the synergistic combination of teniposide (VM-26) and cytosine arabinoside (Ara-C) suggested that a new tool was available for therapy.[7,8]

We designed this treatment protocol with the intent of achieving substantial early cytoreduction using initial multiagent chemotherapy. After delivering prophylactic treatment to the central nervous system (CNS), we administered repeated courses of intensive systemic chemotherapy using alternating courses of several non–cross-resistant drugs. Eligibility was limited to adults aged <50 years because of the anticipated toxicity of the treatment program. This treatment protocol produced a complete remission rate of 94%. By actuarial analysis, we project that 53% ± 9% (SEM) of patients who entered complete remission will remain free of disease at 3 years.

MATERIALS AND METHODS

Patients. Eighty-one consecutive adults with ALL aged <50 years who were seen either at the University of California at San Francisco, City of Hope National Medical Center, Stanford University Medical Center, or by collaborating private physicians in the Bay Area Leukemia Study Group, entered this study between October 1980 and March 1986. During the first 16 months of the study, patients were entered only from the University of California at San Francisco, but beginning in February 1982, patients were entered from all centers. Patients were either previously untreated or had received <2 weeks of therapy with vincristine and prednisone.

Patients were diagnosed as having ALL if morphology was compatible with that diagnosis, if histochemical stains for both peroxidase and α-napthyl butyrate esterase were negative, and if lymphoid markers could be demonstrated. All patients had $>50\%$ blasts in the bone marrow. Immunophenotyping was performed by indirect immunofluorescent techniques using reagents and methods as previously described.[9] The marker used to establish lymphoid lineage was terminal deoxynucleotidyl transferase (TdT) in 72 patients, common ALL antigen (CALLA) in 5 patients, T cell antigen (Leu 1 and Leu 9) in 3 patients, and B cell antigen (BA-1) in 1 patient. Patients were excluded because of prior therapy, presence of Philadelphia chromosome, age >50 years, or diagnosis of B cell leukemia based on L3 morphology and presence of surface immunoglobulin. Central nervous system disease was defined as the presence of any lymphoblasts in cerebrospinal fluid.

Treatment. All patients gave informed consent according to guidelines approved by each institution's Committee on Human Research. Chemotherapy was given in three phases: a remission-induction phase, an intensive alternating combination chemotherapy phase, and a low-dose oral maintenance phase. Remission was induced with daunorubicin, vincristine, prednisone, and L-asparaginase (Table 1). Patients not entering complete remission after 6 weeks of induction chemotherapy were considered to have failed treatment and were taken off study.

Central nervous system prophylaxis was initiated within 1 week of achievement of complete remission. Eighteen hundred rad of cranial radiation were delivered in ten fractions over 12 to 14 days. Six weekly doses of 12 mg of intrathecal methotrexate were administered concurrently. Patients with CNS involvement at diagnosis began their weekly intrathecal methotrexate during induction chemotherapy and received 10 weekly doses. Thereafter, these high-risk patients received intrathecal methotrexate monthly during

Table 1. Remission Induction Therapy

Daunorubicin	50 mg/m^2 IV, days 1-3
Vincristine	2 mg IV, days 1,8,15,22
Prednisone	60 mg/m^2 PO, days 1-28
L-Asparaginase	6,000 U/m^2 IM, days 17-28
If bone marrow on day 14 has residual leukemia:	
Daunorubicin	50 mg/m^2, day 15
If bone marrow on day 28 has residual leukemia:	
Daunorubicin	50 mg/m^2 IV, days 29,30
Vincristine	2 mg IV, days 29,36
Prednisone	60 mg/m^2 PO, days 29-42
L-Asparaginase	6,000 U/m^2 IM, days 29-35

IV, intravenously; PO, orally; IM, intramuscularly.

the first year of therapy, and the dose of cranial radiation was increased to 2,800 rad.

Courses 1, 3, 5, and 7 of consolidation chemotherapy consisted of daunorubicin, vincristine, prednisone, and L-asparaginase (Table 2). Courses 2, 4, 6, and 8 of consolidation chemotherapy consisted of VM-26 and Ara-C. Courses of consolidation chemotherapy were given approximately monthly after the neutrophil count had risen to >1,000/μL and the platelet count to >100,000/μL. The ninth consolidation course consisted of moderate-dose methotrexate and leucovorin rescue.

Maintenance chemotherapy consisted of methotrexate 20 mg/m^2 orally weekly and 6-mercaptopurine 75 mg/m^2 orally daily. Oral maintenance therapy was continued until 30 months of continuous complete remission; all therapy was then discontinued.

Criteria for response. Patients were considered to be in complete remission when the neutrophil count was >1,500/μL, platelet count was >150,000/μL, and results of bone marrow examination were normal. In addition, patients had to be afebrile and have a normal performance status. Mediastinal masses, peripheral lymphadenopathy, and other extramedullary disease had to have completely resolved.

Supportive care. During remission-induction therapy, patients received prophylactic oral nystatin or clotrimazole, as well as trimethoprim-sulfamethoxasole. The trimethoprim-sulfamethoxasole was continued until 30 months of continuous complete remission. Episodes of fever and neutropenia were treated with broad-spectrum antibiotics, usually an aminoglycoside and a semisynthetic penicillin. Platelet transfusions were given prophylactically to maintain the platelet count >10,000/μL, and RBC transfusions were given according to standard transfusion practice. Granulocyte transfusions were not used.

Table 2. Consolidation Therapy

Treatment A (cycles 1,3,5,7)	
Daunorubicin	50 mg/m^2 IV, days 1,2
Vincristine	2 mg IV, days 1,8
Prednisone	60 mg/m^2 PO days 1-14
L-Asparaginase	12,000 U/m^2 IM days 2,4,7,9,11,14
Treatment B (cycles 2,4,6,8)	
Teniposide	165 mg/m^2 IV, days 1,4,8,11
Cytosine arabinoside	300 mg/m^2 IV, days 1,4,8,11
Treatment C (cycle 9)	
Methotrexate	690 mg/m^2 IV, over 42 hours
Leucovorin	15 mg/m^2 every 6 h × 12 doses beginning at 42 hours

Abbreviations as in Table 1.

Statistical analysis. The duration of remission was measured from the time of the remission bone marrow examination. Survival and disease-free survival were measured from the time of initial therapy. Kaplan-Meier analyses of survival and remission duration were calculated with 95% confidence intervals twice the SEM. Statistical tests on prognostic variables for remission duration were performed with the Mantel Cox test.[10] Deaths in remission are treated as relapses, and withdrawals are evaluated up to the time of withdrawal from the study. Data are analyzed as of July 1986.

RESULTS

Patients. The 81 patients ranged in age from 16 to 48 years (median age 24 years) (Table 3). There were 47 male and 34 female patients. No patients were excluded because of their clinical condition.

Included in the study group are several patients with "unfavorable prognostic features," including 7 patients with initial CNS involvement, 14 with mediastinal masses, 12 with WBC counts >100,000/μL, and 6 with WBC counts >300,000/μL. The presence of a mediastinal mass was strongly associated with male sex (13 of 14), high WBC count (median 69,000/μL), and T cell phenotype (11 of 13 tested). In contrast, CNS involvement was not associated with these features; all seven patients had WBC counts <50,000/μL, and only one had the T cell phenotype.

All patients had the diagnosis of ALL confirmed by the presence of at least one immunologic lymphoid marker. Seventy-two of 75 patients (96%) tested were positive for TdT (Table 4). One TdT-negative patient strongly expressed BA-1, and two patients expressed numerous T cell antigens, including Leu 1 and Leu 9. Sixty-four patients (79% of the study group) were extensively immunophenotyped using monoclonal antibodies. Forty of these 63% were CALLA-positive. Three of these patients had anomalous expression of Leu 5 with no expression of the pan-T antigens Leu 1 or Leu 9. These three patients strongly expressed B cell markers (BA-1 or Leu 12) and are classified as B lineage, CALLA-positive. Four other patients expressed B lineage markers (BA-1 or Leu 12) but were CALLA-negative. Five patients are considered to have "null" cell ALL based on the absence of CALLA, B, or T lineage markers. Fifteen patients had T

cell ALL, based on the presence of Leu 1 or Leu 9. Thirteen were E rosette positive (either by rosette assay or presence of Leu 5), and one of these patients was also CALLA-positive. The E rosette-negative T cell patients expressed Leu 1 and Leu 9, respectively. Two of 20 patients tested expressed the myeloid antigens My7 or My9.

Induction of remission. Seventy-six of 81 patients (94%) achieved complete remission. Only one patient failed to achieve hematologic remission. This patient had progressive disease during the second week of chemotherapy and was taken off study. One patient died of asparaginase hepatotoxicity. Three other patients achieved hematologic remission but had persistent systemic candidiasis that precluded their receiving further chemotherapy; they were therefore considered induction failures. Of 76 patients in remission, 41 received 3 doses of daunorubicin, 31 required 4 doses of daunorubicin, and 4 patients had therapy extended to 6 weeks before achieving complete remission.

Duration of remission and survival. Kaplan-Meier analysis projects that 53% ± 9% (SEM) of patients achieving complete remission will remain in continuous complete remission at 3 years (Fig 1). Kaplan-Meier analysis projects that 64% ± 9% (SEM) of all patients will be alive at 3 years (Fig 2). Disease-free survival for all patients entered on study is projected to be 50% ± 9% (SEM) at 3 years (Fig 3).

Of 76 patients in complete remission, 15 have been withdrawn from study, 3 have died in complete remission, and 18 have relapsed (Table 5). Forty patients remain in continuous complete remission (CCR) from 3 to 52 months, with median follow-up of 16 months. Twenty-seven patients have been in remission >1 year, 17 patients have been in remission 2 years, and 8 patients remain in remission >3 years.

Fifteen patients were withdrawn from study. These patients did not have a high incidence of unfavorable prognostic features and were not selected for alternative therapy because of an anticipated poor outcome. Six were treated with bone marrow transplantation, 1 developed anaphylaxis to the initial dose of VM-26, 5 moved or were lost to follow-up, and 3 were withdrawn because of major protocol violations. Two of these violations occurred because the patient refused further therapy; one violation occurred because the physician refused to administer scheduled therapy (despite adequate peripheral blood counts) because of marked bone marrow hypocellularity.

There have been 18 relapses between 1 and 51 months of complete remission. Seventeen relapses occurred in bone marrow. One relapse (in a patient with CNS disease at initial diagnosis) occurred simultaneously in the bone marrow and CNS. Most relapses occurred early, and only three patients relapsed after 19 months. The late relapse at 51 months developed in a patient with transfusion-related AIDS.

Factors that may have influenced remission duration were analyzed (Table 6). Neither age, sex, WBC count, presence of CNS disease, number of doses of daunorubicin required to induce remission, nor immunologic subtype had a significant effect on remission duration (Fig 4).

Toxicity. During remission-induction therapy, all patients had reversible alopecia. Nausea and vomiting were minimal, and stomatitis did not occur. Peripheral neuropathy related to vincristine was usually mild and was significant only in the small group of patients who received 6 weeks of induction chemotherapy.

Side effects related to L-asparaginase were common but were rarely threatening. One patient died during induction therapy of asparaginase hepatotoxicity. One patient developed severe hypersensitivity to the initial dose of *Escherichia coli* asparaginase and was treated with *Erwinia* asparaginase without problems. One patient developed symptomatic pancreatitis. One patient developed severe hepatic and renal toxicity attributed to asparaginase after 7 doses and another received only 10 of 12 planned doses because of progressive lethargy. Subclavian thromboses at the site of the Hickman catheter occurred in three patients. Abnormalities of glucose tolerance and liver function were common but were not considered an indication to discontinue the drug.

Hematologic toxicity of remission-induction therapy was within the expected range. Thrombocytopenia developed in most patients, and 70% required platelet transfusions. The platelets recovered to $>100{,}000/\mu L$ at a median of 18 days. Neutropenia developed in all patients, and 62% were treated with systemic antibiotics other than prophylactic low-dose trimethroprimsulfamethoxasole. There were no infection-related deaths, but three patients failed to respond adequately to amphotericin treatment of systemic candidiasis and could not receive planned consolidation chemotherapy. The median duration of hospitalization for patients during remission-induction was 28 days.

Central nervous system prophylaxis with cranial radiation and intrathecal methotrexate was generally well tolerated. Symptoms of arachnoiditis with headache, nausea, and vomiting developed in 20% of patients, and delayed toxicity of cranial radiation (somnolence syndrome) occurred in 10% of patients.

Consolidation therapy with daunorubicin, vincristine, prednisone, and asparaginase was complicated by fever requiring antibiotics in 10% (21 of 219) of courses. Patients often developed profound neutropenia ($<100/\mu L$), but the duration of severe neutropenia was brief. The median length of these cycles of therapy until the next chemotherapy was 33 days. Several complications of L-asparaginase treatment occurred during these consolidation cycles. One patient developed severe hemorrhagic pancreatitis. She recovered from this episode but died during her next chemotherapy course of noninfectious respiratory failure associated with numerous pancreatic pseudocysts. One patient developed severe hypersensitivity and was subsequently treated with *Erwinia* asparaginase without adverse events. One patient developed massive femoral and iliac venous thrombosis and was successfully treated with streptokinase and heparin. Three patients developed clinical evidence of cardiomyopathy. One had inadvertently received three doses of doxorubicin (50 mg/m^2) during induction chemotherapy and had subsequently received a cumulative dose of 400 mg/m^2 of daunorubicin during consolidation therapy. Two others had received cumulative doses of 600 mg/m^2 of daunorubicin.

Consolidation therapy with VM-26 plus Ara-C was complicated by fever and neutropenia requiring systemic antibi-

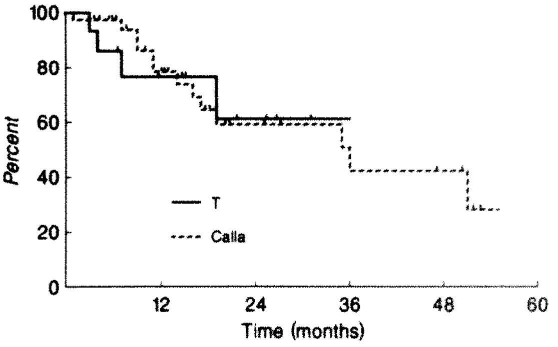

Fig 4. Kaplan-Meier analysis of remission duration by immunophenotype. Tick marks: patients continuing in remission.

otics in 39% (74 of 191) of courses. Profound neutropenia developed in most patients and usually lasted 7 to 10 days. Infections were most commonly caused by enteric gram-negative organisms, but several patients developed *Candida* esophagitis and one patient developed disseminated candidiasis. There were 2 treatment-related deaths, 1 due to noninfectious respiratory failure associated with pancreatic pseudocysts, and 1 due to marantic endocarditis superimposed on underlying rheumatic valvular disease.

The final consolidation therapy treatment with methotrexate was well tolerated. Mild mucositis occurred infrequently, and there was no significant hematologic toxicity. Oral maintenance therapy was generally well tolerated. However, the majority of the patients received 75% of the planned dose because of hematologic toxicity, and one patient with cardiomyopathy died of infection.

Median hospitalization time during the entirety of post-remission-induction therapy was 19 days. Four of these days were required for administration of the methotrexate infusion, and 15 days were required for antibiotic treatment of episodes of fever and neutropenia. Patients thus spent a median of 47 days in the hospital during the entire period of treatment.

DISCUSSION

The question of the criteria for the diagnosis of adult ALL is a difficult one. The results of the treatment program may be critically dependent on the population studied. The diagnosis of ALL is not as straightforward in adults as it is in children, since the typical L1 morphology is apparent in only 20% to 30% of cases. We used available diagnostic techniques to define our ALL population as accurately as possible. We required not only that cells fail to exhibit myeloid characteristics by histochemical stains, but also that the cells be positively identified as lymphoid by an immunologic technique. This was done in an attempt to exclude occult cases of acute myeloid leukemia that would exhibit peroxidase positivity only at an ultrastructural level.[11]

Our patient group is representative of most groups of adult ALL. No patients were excluded because of their clinical condition. Included in our treatment group are several patients traditionally defined as having poor prognostic features. Seven patients initially had CNS involvement, 12 patients had WBC counts $>100{,}000/\mu L$, and 6 patients had extreme hyperleucocytosis with WBC counts $>300{,}000/\mu L$. Seventy-nine percent of patients were extensively immunophenotyped using monoclonal antibodies. The most common reason for failure to phenotype was inaspirable bone marrow with low circulating blast counts. We were able to phenotype some of these patients, however, using in vitro antibody binding to biopsies placed in saline.[12] The distribution of immunologic subtypes of ALL in our study is similar to that in other reported series (Table 4). Sixty-three percent of patients studied were classified as "common" ALL, and 23% had T cell disease.

The goal of our induction chemotherapy was to achieve normal bone marrow function (complete remission) as quickly as possible without undue toxicity. The importance of avoiding toxicity is highlighted by the fact that, in the past, more induction failures had been due to therapy-related complications than to chemotherapy-resistant disease.[13-15] On the other hand, early studies at St Jude's Hospital suggested that the results of the early phases of treatment were critical in determining overall outcome and that more intensive subsequent treatment may not be able to overcome poor initial cytoreduction.[1] Recently, the importance of intensive induction chemotherapy was demonstrated by two groups treating childhood ALL.[16] In one prospective randomized clinical study of childhood ALL, the addition of an anthracycline to the remission-induction program improved long-term disease-free survival from 39% to 64%.

At a minimum, an optimal remission-induction program for adult ALL should include an anthracycline in addition to vincristine and prednisone. The Cancer and Leukemia Group B recently demonstrated in a randomized prospective study that adding daunorubicin to vincristine and prednisone increased the remission rate from 47% to 78%.[17] Although the period of neutropenia was increased by the addition of daunorubicin, no increase in either severe or fatal infections occurred in the more intensively treated group. One may actually be able to reduce overall toxicity by achieving complete remission more rapidly, thereby avoiding prolonged pancytopenia caused by the sequential addition of increments of therapy. Several other recent studies showed that the combination of daunorubicin, vincristine, and prednisone consistently produced a complete remission of ~80% in adult ALL.[18,19]

Given the complete remission rate of 80% using daunorubicin, vincristine, and prednisone, and the relatively small number of patients with adult ALL available for study, one cannot demonstrate a remission-induction advantage to the addition of asparaginase to this program.[20-25] Asparaginase can, however, be a useful agent for remission induction, and the best reported results for remission induction in children with relapsed ALL have been produced by four-drug regimens that included asparaginase.[26,27]

Our remission-induction program has been very successful, with 94% of patients entering complete remission. The toxicity of the program was not severe, and profound neutropenia usually lasted only several days. Systemic antibiotics were needed in only 62% of patients, and life-threatening infections were not common. Patients were generally in excellent clinical condition at the completion of induction therapy and could proceed directly to consolidation therapy without delay.

One novel aspect of our treatment program was the repeated use of VM-26 and Ara-C in consolidation therapy. It was the early experience with this synergistic combination that prompted the design of this study. In early studies, VM-26 produced a low response rate when used as a single agent. Increasing the dose and adding vincristine and prednisone produced a 30% remission rate in children with relapsed ALL, however.[28] VM-26 given in combination with Ara-C, produced exciting results.[7,8] In one study, 3 of 4 patients who failed to respond to initial intensive induction therapy entered complete remission, and 2 of these patients remained in remission 30 months later when they completed therapy. To have produced this disease-free survival in patients with a dismal prognosis was unprecedented, and suggested that this combination would be a major addition to our therapeutic armamentarium. Further studies suggested a beneficial role for VM-26 plus Ara-C as consolidation therapy for ALL. One report demonstrated that the addition of a single consolidation course with these agents prolonged remission duration and produced more long-term disease-free survivors.[29] This, however, was not confirmed in a second study.[30] Repeated courses of VM-26 plus Ara-C have improved the outcome in high-risk pediatric ALL.[31]

Alternating with cycles of VM-26 plus Ara-C, we treated patients with a four-drug program that included asparaginase in a total dose of 72,000 U/m^2. We chose this dose of asparaginase based on dose–response relationships established in pediatric ALL.[32,33] Few adult treatment programs have used repeated large doses of L-asparaginase,[34] and this represents a second novel aspect of our treatment program. The potential usefulness of asparaginase in consolidation therapy in children has been demonstrated by a randomized study showing longer disease-free survival in asparaginase-treated patients.[35]

One of the goals of the study was to determine if more effective therapy would change the significance of factors previously reported to be of prognostic importance in adult ALL. We particularly wondered if more effective therapy would diminish the importance of adverse prognostic features. Most reported studies of adult ALL show a strong prognostic significance for WBC count at diagnosis.[13,18,20,21,25] The prognostic significance of immunologic subtype has been variable.[13,18,20,21,36] At this point in our analysis, neither age, sex, WBC count, nor immunologic subtype has prognostic significance with respect to either remission induction or remission duration. Our assessment of prognostic factors differs from those of previous studies. Because many of our patients are still at risk for relapse, however, it is too early to draw firm conclusions from this analysis.

Intensified chemotherapy has been convincingly shown to improve the outcome in high-risk pediatric ALL.[37] Our treatment results are very encouraging and add to the increasing evidence that intensive treatment has improved the long-term outcome of adult ALL as well. During the 1970s, only 15% of adult ALL patients remained disease-free at 5 years. The L10 protocol at Memorial Hospital now has a large enough patient group and long enough follow-up to be confident that results of treatment have indeed improved.[13,18] Thirty-five percent to 40% of all patients entered are projected to remain disease-free at 5 years, and most are probably being cured of their disease.

In conclusion, we have developed an intensive treatment program for adult ALL that has been successful in improving disease-free survival. Although our treatment program is prolonged, the intensive phase is completed in 11 months and subsequent oral maintenance therapy is very well tolerated. The program was carried out at several different institutions as well as by private physicians and was relatively easy to administer. Patients spent <7 weeks in the hospital during all therapy. Although longer follow-up will be necessary to determine the ultimate impact of this program, we are hopeful that a substantial fraction of patients will be cured of their disease.

In Vitro Tests That Predict Tumor-Associated Idiotype Levels in the Serum of Patients With B Cell Lymphomas and Leukemias

By Richard A. Miller, James N. Lowder, Julie Gralow, Timothy Meeker, and Ronald Levy

The presence of circulating tumor idiotype interferes with the in vivo effectiveness of anti-idiotype antibodies. We developed two assays that permit identification of patients with high levels of serum idiotype without the need for first producing an anti-idiotype antibody. A cell suspension made from the tumor was cultured for seven days with or without phytohemagglutinin (PHA) and/or phorbol myristic acetate (PMA). Ig secretion in vitro by patients' tumor cells varied. In 4 patients, no secretion in vitro occurred, 5 patients had low levels, and 5 patients had high levels of Ig secretion. In three patients, Ig secretion occurred only after stimulation with PHA, PMA, or both. Spontaneous or induced immunoglobulin secretion in vitro is related to the levels of tumor idiotype secretion that exist in vivo. Eight patients with serum idiotype levels $>100\ \mu g/mL$ (mean 265 $\mu g/mL$), had a minimum of 1.0 $\mu g/10^6$ cells of idiotype secretion in vitro. Nine patients with serum idiotype levels $<30\ \mu g/mL$ (mean 3.7 $\mu g/mL$), had $\leq 0.5\ \mu g/10^6$ cells of idiotype secretion in vitro. In another assay, the levels of IgM κ and IgM λ in patients' sera were compared with those in normal serum. An imbalance in the relative amounts of IgM κ and IgM λ indicated high levels of circulating idiotype in the serum, but this assay was less sensitive than the in vitro secretion assay and limited to IgM-secreting tumors. These assays will be useful for future clinical studies using anti-idiotype antibodies.

MOST MALIGNANT lymphoproliferative diseases that occur in humans are derived from B lymphocytes and synthesize an immunoglobulin (Ig) with a unique combination of a V_L and V_H region, and a light chain of either the κ or λ type.[1,2] Antigenic determinants unique to these Igs are called idiotypes and represent a specific marker for that tumor. In some diseases, eg, multiple myeloma and Waldenstrom's macroglobulinemia, the malignant cells secrete large amounts of Ig. In most cases, however, the Ig is expressed on the cell surface without significant secretion.[3] We and others prepared antibodies against tumor idiotypes and showed that such reagents are useful for studies of the immunobiology of these diseases.[4-9] Antiidiotype antibodies can also be used to monitor tumor growth in humans and in experimental animals.[10-12] For several reasons, anti-idiotype antibodies offer promise as therapeutic agents. Animal studies and human therapeutic trials have demonstrated the potential for this approach.[4,6,8,9,13,14] Our own therapeutic trials in 14 patients with B cell lymphomas using monoclonal anti-idiotype antibodies demonstrated variable results.[9,15] In one case, a complete and durable remission was achieved. In other cases, partial responses occurred.[8,9] In these studies, the presence of circulating tumor idiotype interfered with the therapeutic use of anti-idiotype antibody. In addition to blocking the anti-idiotype antibody from binding to cellular antigen, circulating idiotype–anti-idiotype complexes led to toxicity.

To avoid these problems, one should select patients with little or no circulating idiotype. Conventional serologic techniques, such as serum protein electrophoresis or quantitative Ig levels, will exclude the minority of patients with very high levels of paraprotein but are not sensitive enough to detect levels of serum idiotype $<200\ \mu g/mL$, which are capable of interfering with anti-idiotype therapy.

We developed in vitro techniques that allow prediction of the level of tumor idiotype in a patient's serum. These techniques are particularly valuable because they do not require availability of an anti-idiotype antibody.

MATERIALS AND METHODS

Patients and preparation of tissues. Eighteen patients with established histopathologic diagnoses of B cell malignancies were included in these studies (Table 1). Patients were selected who had tumor tissue readily accessible to biopsy and expected survivals of >1 year. Cell suspensions were made either from lymph nodes obtained by biopsy or from spleens removed during laparotomy. In patients with leukemia, peripheral blood was used as the source of tumor cells. After isolation of mononuclear cells using Ficoll-Hypaque centrifugation, cells were suspended in medium containing 10% dimethyl sulfoxide (DMSO) and cryopreserved in liquid nitrogen. Immunophenotyping was performed either on fresh cells or on cells that had been stored in liquid nitrogen. Monoclonal fluorescein conjugated anti-Leu-4 (Becton Dickinson Monoclonal Center, Mountain View, CA) was used to identify normal mature T cells. Affinity-purified fluorescein-conjugated $F(ab)_2$ fragments of goat anti-human Ig heavy and light chains (Tago, Burlingame, CA) were used to identify normal and malignant B cells. Immunofluorescence staining and analysis using a fluorescence-activated cell sorter (FACS IV, Becton Dickinson, Sunnyvale, CA) were described previously.[9,16] At the time of biopsy, patients' sera were obtained by venipuncture, separated from clotted whole blood by centrifugation at 1,000 g, and stored at −20°C.

Spontaneous or induced secretion of Ig in vitro. Patient cells were thawed, and viable mononuclear cells were isolated by Ficoll-Hypaque separation. Viability proved >95% after centrifugation, as measured by trypan blue dye exclusion. One million cells per milliliter were resuspended in RPMI 1640 medium containing 15% fetal calf serum (FCS) (GIBCO, Grand Island, NY), L-glutamine, sodium pyruvate, penicillin, streptomycin, and 10^{-4} mol/L of 2-mercaptoethanol. One milliliter of the patients' cell suspensions was

placed in each of four wells in a 24-well tissue culture plate (Costar, Cambridge, MA). Either 1.0 μg of phytohemagglutinin (PHA, Burroughs Wellcome, Research Triangle, NC) or 10 ng of phorbol myristic acetate (PMA, Sigma, St Louis) or a combination of both at the same final concentrations were added to individual wells. Control and stimulated cultures were maintained in a humidified 37°C, 5% CO_2 atmosphere in an air incubator for seven days. Kinetic studies were first done to determine the optimal incubation time at which to assay for Ig secretion.

Immunoglobulin assay. The amount of Ig in culture supernatants was measured using an enzyme-linked immunosorbent assay (ELISA). Polystyrene microtiter plates (96-well) (Immulon I, Dynatech, Alexandria, VA) were coated with 50 μL/well of affinity-purified goat anti-human Ig (Tago) at a concentration of 10 μg/mL in phosphate-buffered saline (PBS). After the cell cultures were washed with PBS containing 0.05% NP-40 (Sigma), 50 μL of culture supernatants, serially diluted in 1% bovine serum albumin (BSA) in PBS, was added to the wells for one hour at room temperature. The plates were washed again, and 50 μL of horseradish peroxidase (HRP) conjugated, affinity-purified, goat anti-human κ or λ light chain-specific antibodies (Tago) was added for one hour at room temperature. After the cultures were washed, 100 μL of a solution of 2, 2'-azino-di-(3-ethyl-benzthiazoline-sulfonate) (ABTS, Sigma) in 0.05 mol/L of sodium citrate buffer pH 4.0 with 0.01% hydrogen peroxide was added. Color development was determined by measuring the optical density (OD) at 405 nm using an MR600 microplate reader (Dynatech). From the mean OD, the amount of Ig was calculated from a standard curve produced using purified human Igs. Although some assays were done on different days, the amount of Ig was always calculated based on simultaneously run standards. The sensitivity of this assay was 0.01 μg/mL.

Assay for IgM κ and λ light chains. Polystyrene microtiter plates were coated with 10 μg/mL of goat anti-human IgM (Tago) in PBS. The plates were washed as above and then incubated for one hour at room temperature with 5% instant milk (Carnation Nonfat Dry Milk, Los Angeles) in PBS. This blocking step was found to increase the sensitivity of the assay greatly by reducing the background. After another wash, the patients' sera were added by doubling dilutions with PBS containing 1% BSA (PBS–BSA) into 16 wells. The plates were incubated for one hour at room temperature and washed again. Horseradish peroxidase-conjugated affinity-purified goat anti-human κ or λ light chain-specific antibodies (Tago) were added. After one-hour incubation at room temperature and another wash, an ABTS solution was added and color development was measured as described above. This assay was performed simultaneously on the test samples and pooled normal human serum (HS, eight donors). Titration curves were generated, and the 50% saturation points were compared. The serum dilutions at these points were expressed as a percentage of the normal pooled HS. The amounts of IgM κ, relative to pooled normal HS, was then compared with the amount of IgM λ, relative to pooled normal HS.

Anti-idiotype antibodies. Murine monoclonal anti-idiotype antibodies were produced as previously described.[17] Either purified idiotypic protein or whole tumor cells were used to immunize mice used in the making of anti-idiotype antibody-secreting hybridomas. The candidate anti-idiotypes were screened for nonreactivity with three different purified human IgM proteins and human tonsil. The antibodies used in these studies were purified from ascites.

Measurement of tumor-specific serum idiotype. An ELISA assay used to measure the concentration of serum idiotype was described previously.[9] The microtiter plates (Dynatech) were coated with specific anti-idiotype antibody at a concentration of 10 μg/mL in PBS NP-40. After the plates were washed, idiotype protein standard and unknown samples were serially diluted with PBS-BSA in parallel on the plate, incubated, and washed again. Biotin-conjugated specific monoclonal anti-idiotype antibody was added, incubated, and washed from the plate. Avidin conjugated to HRP (Vector, Burlingame, CA) was added at an appropriate dilution, incubated, and washed. ABTS was added as a final step, and the results were evaluated as in the immunoglobulin assay described above.

RESULTS

Characteristics of patients and tissues. Table 1 lists the 18 patients selected for these studies. All patients had advanced disease with easily palpable lymphadenopathy in multiple anatomic sites and/or large numbers of tumor cells in their peripheral blood. Lymphoma patients had stage III or IV disease; leukemic patients had WBC counts >25,000/μL, and most cells were malignant. Eleven of the 18 patients had received prior treatment with chemotherapy and/or radiotherapy. No patient had received therapy within 1 month of tissue sampling or serum collection. The sources of tissue were lymph node in 10 patients, peripheral blood in 5 patients, and spleen in 3 patients who underwent splenectomy for diagnosis (C.B.) or because of cytopenias or symptomatic organomegaly (J.C., C.G.).

The surface Ig type was established by immunofluorescence staining and FACS analysis of cell suspensions. In each case, except that of D.H., a predominant light chain type was found. Thus, these cases were believed to be monoclonal. These results were confirmed on frozen tissue samples using an immunoperoxidase technique.[16] In D.H., the peripheral blood lymphocytes expressed either κ or λ light chain in approximately equal ratios.

The percentage of malignant cells and infiltrating normal T cells within the tissue are also shown in Table 1. These percentages were determined using immunofluorescence on the FACS gated on the lymphoid population of cells. The degree of tumor involvement was >50% in the specimens of 17 of 18 patients. One patient's (P.E.) biopsy had only 21% tumor cells, with a strikingly large number of normal T cells (76%).

Secretion of tumor idiotype in vitro. Cell suspensions from tumor specimens were cultured with or without PMA and/or PHA. The optimal concentration of PMA (10 ng/mL) and time to measure secreted Ig in the culture supernatant (day 7) were determined in preliminary studies. Subsequently, cumulative Ig secretion was measured after a seven-day culture period (Table 2). Four patients (T.G., B.J., C.J., and C.P.) had undetectable amounts of Ig in control and in stimulated cultures. Five patients (R.B., K.C., N.D., C.G., and D.S.) had low levels of spontaneous or induced Ig secretion. The remaining nine patients had higher levels of secreted Ig. Three patients (R.P., L.R., and M.V.) had no detectable spontaneous Ig secretion, but significant quantities were secreted on stimulation with PMA, PHA, or both. Five patients (J.C., P.E., D.H., B.L., and F.S.) had high levels of spontaneous Ig secretion only minimally affected by stimulation.

Table 2. Secretion of Tumor Id In Vitro and In Vivo

	In Vitro Secretion (μg/mL)

Id, idiotype; PMA, phorbol myristate acetate; PHA, phytohemagglutinin. 0, none detectable; NM, not measured; NA, not applicable because tumor secreted IgG.

*Secretion of both light chain classes was observed. Values for both are listed.

In all but one case, only a single type of secreted light chain was detected. This always matched the light chain type found on the surface of the tumor cells. In D.H., both κ and λ light chains were found in culture supernatants. Immunoglobulin gene rearrangement studies showed that patient D.H. was biclonal as was reported previously.[18] His tumor was comprised of a mixture of κ-and λ-bearing clones.

Correlation of secretion in vitro with serum idiotype level. Table 2 also shows the amount of tumor idiotype measured in the serum of these patients at the time of tissue sampling. The levels of serum idiotype correlated with the spontaneous or induced secretion of Ig in vitro (Fig 1). Patients with spontaneous or induced levels of secreted Ig ≥1.0 μg/mL had high serum idiotype levels (mean ± SD 265 μg/mL ± 172) as compared with patients with secretion in vitro ≤0.5 μg/mL (mean ± SD 3.7 μg/mL ± 9.9). Distribution of serum idiotype levels between these two groups did not overlap. The measurement of spontaneous or induced Ig secretion in vitro accurately identified patients with high serum idiotype levels. There was no correlation between the numbers of normal T cells within the tumor sample and the amount of spontaneous or induced Ig secretion in vitro (Tables 1 and 2). Further analysis of T cell subsets revealed no consistent pattern (data not shown).

Analysis of serum IgM for κ and λ light chain. Most B cell lymphomas express IgM on their cell surface and would secrete antibody with that heavy chain isotype. The total amounts of IgM κ and IgM λ in the serum of most of the patients were below those found in pooled normal serum. This finding is a result of the hypogammaglobulinemia that frequently exists in patients with B cell lymphoma. An assay that measured the concentration of κ and λ light chains in the IgM component of serum was developed. The values were compared with those in pooled normal human serum; a calibration of this assay is shown in Fig 2. Various concentrations of either a purified IgM κ or IgM λ paraprotein were added to pooled human serum and compared with the unspiked serum. A minimum level of paraprotein of 200 μg/mL was detectable in this assay. Higher levels caused an

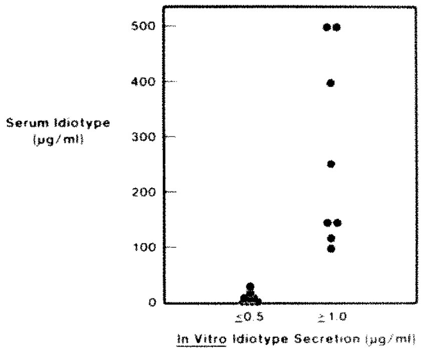

Fig 1. Correlation of in vitro secretion of Ig with serum idiotype level. Tumor cells secreting ≤0.5 μg/mL of Ig in vitro were from patients with ≤30 μg/mL of serum idiotype. In vitro secretion of ≥1.0 μg/mL predicted ≥100 μg/mL of serum idiotype.

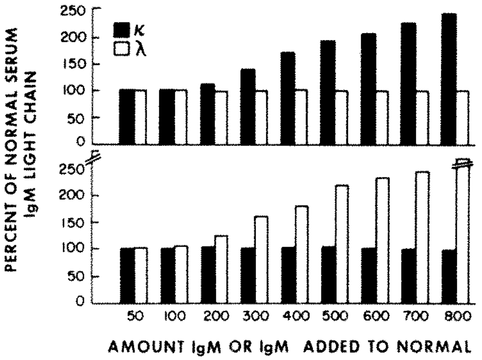

Fig 2. Sensitivity of κ/λ ratio assay for the presence of IgM paraprotein. Increasing amounts of purified $\mu\kappa$ (top) or $\mu\lambda$ (bottom) Ig were added to normal human serum and assayed as described in the Materials and Methods section. SD was <10% both in repeated assays and when different sources of normal human serum were used.

increasingly greater excess of light chain in the test serum as compared with the unspiked serum. As expected, the non-paraprotein–associated light chain levels remained constant in all the test samples. Patients with IgG-secreting tumors were tested using a similar assay. The large amounts of normal IgG in serum obscured the results.

This assay was performed on serum from 14 patients, as shown in Fig 3. Seven patients (C.B., P.E., B.L., R.P., L.R., F.S., and M.V) had an imbalance in the amounts of light chains as compared with patients having normal serum. This is best demonstrated in patient R.P., who had a monoclonal IgM κ protein spike detected by serum protein electrophoresis. Using this assay, we found more IgM κ in the patient's serum than in the normal serum; however, the IgM λ level was quite low. This caused a dramatic imbalance in the levels of IgM light chains as compared with those in normal serum. Similar, but less dramatic, results were obtained in six other patients. Each of these seven patients had high levels (>100 μg/mL) of idiotype in the serum. The other seven patients had no significant imbalance in IgM light chains and had serum idiotype levels <15 μg/mL. As compared with the data shown in Fig 2, detectable levels of circulating monoclonal proteins were lower in the patient's serum (100 μg/ml in C.B.) than in normal serum. This is likely related to the lower background IgM levels, which made it easier to detect small amounts of the monoclonal Ig. This assay successfully predicted which patients secreted $\geq$100 μg/mL of idiotype into the serum, provided that the idiotype was IgM.

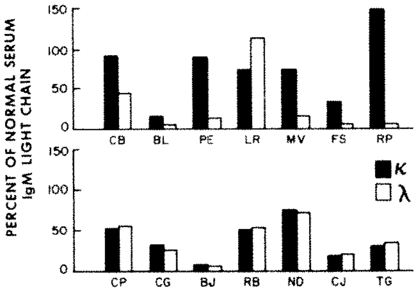

Fig 3. Results of the κ/λ ratio assay. Patients with serum idiotype levels of >15 μg/mL (top) and patients with serum idiotype levels of <15 μg/mL (bottom) are shown, with increasing idiotype levels from left to right. The minimum serum idiotype among the >15 μg/mL group was 100 μg/mL (C.B.).

DISCUSSION

Because a custom-made antibody must be made for each patient, criteria must be established that will facilitate the selection of the most favorable candidates for anti-idiotype therapy. Circulating antigen interferes with therapy using antibodies.[4,6,9,19] This has been a particularly important problem in studies using anti-idiotype antibodies directed against the Ig present on B cell tumors.[4,6,9] Patients with insurmountable levels of idiotype in their serum should be excluded from therapeutic trials. In the past, an anti-idiotype antibody first had to be produced; it could then be used to measure the level of circulating idiotype protein. In this study, we developed in vitro assays that predict which patients have significant levels of serum idiotype without using an anti-idiotype reagent.

We prepared monoclonal anti-idiotype antibodies for all the patients studied in this report except D.H. This enabled us to measure idiotype levels accurately in these patients to establish a correlation with in vitro predictive tests. Several factors may have influenced both the in vitro assay results and the in vivo idiotype levels. The number of cells added to each well of the in vitro assays was based only on viable cells, with no adjustments made for the cellular composition, ie, the ratio of tumor, normal B cells, and normal T cells. Thus, the number of Ig-secreting cells in each well were proportionately reduced in tumors with large numbers of T cells. In addition, the T cells may influence, either positively or negatively, the ability of the malignant B cells to secrete Ig. Finally, the in vivo level of serum idiotype varies directly with tumor bulk.[11] Despite these theoretical problems, the in vitro assays reliably predicted in vivo levels.

The effects of various mitogens, including PHA and phorbol esters, on secretion of immunoglobulin by normal and neoplastic B cells were previously studied in vitro.[20-28] PHA added to cultures of normal T and B cells caused proliferation of both sets of cells, expression of interleukin 2 (IL2) receptor on the T cells, and increased secretion of Ig by B cells. Most of these effects were mediated by soluble B cell growth and differentiation factors secreted by the stimulated T cells. The mitogens produced both increased secretion of Ig and maturation of the malignant cells, as measured by switch of idiotype-positive IgM and IgD to IgG.[21,22] No correlation with the in vivo secretion of the malignant cells has been previously reported. Although a direct effect of the mitogens on the tumor cells produced some enhancement of secretion, their effect on T lymphocytes, also present in the culture, was probably more important.[23] Defects in the in vitro function of the T lymphocytes of patients with B cell malignancies have been identified.[23-28] Some reports showed that allogeneic cells were far better at stimulating secretion of Ig than were autologous T cells.[23,25,26] Indeed, suppression was induced by adding back autologous T cells to a culture containing normal allogeneic T cells and the malignant B cells.[26] Other investigators were unable to identify abnormal T cell suppression.[27,28] We found no correlation between the numbers or types of T cells and spontaneous or induced Ig secretion among the tumors in this study.

The autologous T cells may have suppressed production in the patients whose tumors secreted little or no Ig in vitro or in vivo. Among those that secreted Ig in vitro, however, our data suggested an enhancing effect of T cell stimulation on Ig secretion. Differences were evident among the patients regarding the necessity for PHA and/or PMA to produce maximal secretion of Ig. In patients R.P. and L.R., PMA and PHA had a synergistic effect on idiotype secretion. PMA induces IL 2 receptor expression on T cells.[26] This effect, together with the T cell proliferation induced by PHA, may have led to amplification of synthesis and secretion of B cell growth and differentiation factors. Patient R.P. had the highest level of secretion in vitro (Table 2, >3.0 μg/mL), but only after stimulation with both PMA and PHA. Serum protein electrophoresis (SPEP) showed that this patient had a paraprotein spike of 20 mg/mL, suggesting that T cells were necessary for tumor idiotype secretion in vivo as well as in vitro. Similar observations were made for L.R. and M.V., who also had high levels of serum idiotype. Previously, we reported that the absolute number of T cells in the tumor correlated positively with the patient's response to anti-idiotype therapy.[15] T cells located within the tumor or elsewhere may regulate the in vivo secretion of idiotype as well as the control of growth and differentiation of the malignant B cells.

The assay to measure spontaneous and induced secretion of Ig was designed to correlate with in vivo secretion and thus with serum idiotype. The effects of autologous T cells were not eliminated in this assay, so that we could simulate the in vivo situation. Although this assay measured free light chains and IgG as well as IgM, we believe that quantitation of the total Ig secreted in vitro is important in determining the in vivo secretory capacity of the tumor cells. The assay was successful in this respect. The spontaneous or induced secretion of idiotype was able to identify patients with high serum idiotype levels (Fig 1). In vitro secretion <0.5 μg/mL can be used to select patients with little or no circulating idiotype. Conversely, in vitro secretion of >1.0 μg/mL identifies patients with high levels of serum idiotype who are not good candidates for anti-idiotype therapy.

We also tested an assay that measures the relative imbalance of IgM light chains in the serum to detect circulating IgM tumor idiotype. The advantage of this test is that culture of cells is not required and results may be obtained rapidly. Although the assay successfully identified patients with large amounts of IgM, its lack of sensitivity and inapplicability to IgG-secreting tumors limited its usefulness.

Other workers have isolated tumor idiotype either from serum or from cultures of malignant cells.[26] Although these techniques simplify the process of making anti-idiotype antibodies, it requires patients with high levels of serum idiotype. Thus, these methods have the disadvantage of selecting for the most unfavorable patients.

Our studies have considerable practical significance. The ability to select patients with low levels of serum idiotype will facilitate therapeutic studies using anti-idiotype. Our studies may also be useful in monitoring tumor activity and response to treatment. In addition to their practical importance, our studies have important implications regarding the immunoregulation of B cell tumors.

CONCISE REPORT

Mother-to-Offspring Transmission of Human T Cell Leukemia Virus Type I in Rabbits

By Yoshiki Uemura, Shigemitsu Kotani, Shizuo Yoshimoto, Masatoshi Fujishita,
Makoto Yamashita, Yuji Ohtsuki, Hirokuni Taguchi, and Isao Miyoshi

We studied the mode of natural transmission of human T-cell leukemia virus type I (HTLV-I) in rabbits. Four virus-infected rabbits (2 males and 2 females) were individually mated with 4 noninfected rabbits. Two virus-infected females mated with noninfected males gave birth to 7 offspring, and 2 noninfected females mated with infected males delivered 5 offspring. Four of the seven offspring born to the virus-infected mothers seroconverted for HTLV-I when aged 6 to 13 weeks with antibody titers of 1:40 to 1:160. None of the five offspring born to the noninfected mothers became seropositive during the observation period of 6 months, however. Peripheral lymphocytes were cultured with T cell growth factor, and HTLV-I-carrying lymphoid cell lines were established from the four seroconverted rabbits. All four cell lines were of T cells positive for Ia antigens. In addition, none of five newborn rabbits killed immediately after birth to a virus-infected rabbit was infected with HTLV-I. These findings provide an experimental support for the milkborne transmission of HTLV-I from mother to child in humans and indicate that the virus is tropic for T cells in rabbits as well.

© 1987 by Grune & Stratton, Inc.

THE HUMAN T-cell leukemia virus type I (HTLV-I) is an exogenous type C retrovirus etiologically associated with adult T cell leukemia (ATL).[1] The virus is transmissible by blood transfusion.[2] Seroepidemiologic surveys suggest natural transmission of HTLV-I from mother to child and between spouses.[3,4] Detection of viral antigens in semen and mothers' milk indicate that the virus was transmitted by sexual contact and by breast feeding.[5,6] Recently, HTLV-I was shown to be transmissible to marmosets by oral inoculation of virus-infected lymphocytes from ATL patients[7] and by feeding of milk from seropositive women.[8] We showed that rabbits could be infected with HTLV-I intravenously,[9] orally,[10] and by blood transfusion.[11] We now report natural transmission of HTLV-I from mother to offspring in this animal model.

MATERIALS AND METHODS

Animals. Non-inbred Japanese white rabbits weighing ~3 kg were used. They were purchased from a commercial breeder and received pelleted diet and tap water. Two females and two males were infected with HTLV-I by transfusion of 20 mL of blood from virus-infected rabbits, as described previously.[11] All four rabbits seroconverted for HTLV-I after 2 to 4 weeks, and their antibody titers ranged from 1:80 to 1:640 in an immunofluorescence assay. The four virus-infected rabbits were housed individually and were mated with four noninfected rabbits.

Detection of antibodies to HTLV-I. Rabbits born to the virus-infected parents were followed for the development of antibodies to HTLV-I. Blood samples were taken first when the rabbits were aged 4 weeks and then serially at intervals of 1 to 2 weeks for 6 months. Sera were titrated for HTLV-I antibodies by indirect immunofluorescence[12] using the MT-2 cell line.[13] In brief, acetone-fixed MT-2 cells were first reacted with appropriately diluted rabbit sera and then with fluorescein-conjugated (FITC-conjugated) swine anti-rabbit immunoglobulins (DAKO, Copenhagen) for 30 minutes at 37°C. Anti-HTLV-I positive and negative rabbit reference sera were included as parallel controls.

Cell culture. Lymphocytes were separated from 10 mL of blood by Ficoll-Hypaque gradient centrifugation. The cells were cultured at 1×10^6/mL in 35-mm Petri dishes with RPMI 1640 medium supplemented with 20% fetal calf serum (FCS), 10% crude T cell growth factor (TCGF) (Japan Immunoresearch Laboratories, Takasaki), and antibiotics. The cultures were incubated at 37°C in a humidified 7.5% CO_2 atmosphere and fed twice a week.

Analysis of surface and antigen markers. Cells were examined for sheep erythrocyte (E) receptors, as described previously.[14] Surface immunoglobulins (SIg) were tested by reacting cells with FITC-conjugated swine anti-rabbit immunoglobulins. They were also tested by membrane immunofluorescence for reactivities with monoclonal antibodies, including Leu-1 (human T cells), OKIa1 (human Ia antigens), L11/135 (rabbit T cells),[15] and 2C4 (rabbit Ia antigens).[16] HTLV-I antigens were detected by indirect immunofluorescence with reference ATL patient's serum and anti-p19[17] and anti-p24[18] monoclonal antibodies.

RESULTS

Seroconversion in offspring of HTLV-I–infected rabbits. Four pairs of male and female rabbits each delivered one litter of 1 to 6 newborns. Two virus-infected females mated with noninfected males gave birth to 7 offspring, and 2 noninfected females mated with virus-infected males gave birth to 5 offspring (Fig 1). Four of the 7 rabbits born to the virus-infected mothers seroconverted for HTLV-I at 6 to 13 weeks after birth. Their antibody titers, initially low at 1:10, rose to the highest levels of 1:40 to 1:160 over the following 2 to 8 weeks and remained at those levels thereafter (Fig 2). In contrast, none of the 5 rabbits born to the noninfected

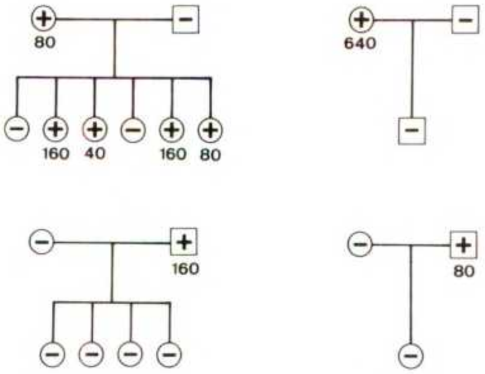

Fig 1. Parent-to-offspring relationship with respect to seroconversion (+) in rabbits. Males (□); Females (○). Numbers below symbols denote final antibody titers to HTLV-I. Seroconverted offspring (left to right) yielded HTLV-I–carrying lymphoid cell lines Ra-7 to Ra-10, respectively.

mothers became seropositive during the observation period of 6 months.

Isolation of HTLV-I from seroconverted offspring. When the rabbits were aged 3 to 4.5 months, blood samples were taken from the seven offspring born to the virus-infected mothers; their lymphocytes were cultured in the presence of TCGF. Active cell growth occurred after 2 to 4 weeks and a TCGF-dependent lymphoid cell line was established from each of the four seroconverted offspring, whereas the cells from the three seronegative offspring did not grow for >2 months. These four cell lines, designated Ra-7 to Ra-10, grew in suspension with clumps of cells and consisted of primitive lymphoid cells (Fig 3). Two of the four cell lines became TCGF-independent after 2 months. The four cell lines had a normal female rabbit karyotype corresponding to the sex of the donors. All four cell lines were reactive with L11/135 and 2C4 but were completely negative for E receptors, SIg, Leu-1, and OKIa1. HTLV-I antigens were fully expressed in all the cell lines as detected with reference ATL patient's serum, anti-p19, and anti-p24. Type C virus particles were demonstrated in these cell lines by electron microscopy (Fig 4). These characteristics are shown in Table 1.

Examination of newborn rabbits for HTLV-I infection. A litter of five newborn rabbits was killed immediately after birth to a virus-infected rabbit, and their splenic lymphocytes were cultured in the presence of TCGF. All five cultures were negative for HTLV-I antigens when examined by indirect immunofluorescence after 3 to 4 weeks and eventually failed to be established as lymphoid cell lines.

DISCUSSION

The concept of mother-to-child transmission of HTLV-I has been previously supported on seroepidemiologic grounds[3,4] by the detection of viral antigens in milk from seropositive women,[5,6] and by experimental oral transmission of HTLV-I into marmosets.[7,8] A rabbit model of HTLV-I infection provided a unique opportunity to investigate the mode of transmission of this virus.[9-11] In the present experiment, virus-infected female rabbits were mated with noninfected male rabbits and vice versa, and their offspring were followed for evidence of virus infection. Virus transmission occurred in offspring born to virus-infected mothers but not in offspring born to noninfected mothers. These findings give experimental support for the natural transmission of HTLV-I from mother to child in humans.

Two routes of virus transmission, transplacental or milk-borne, may be considered. To clarify this point, we attempted

a foster-nursing experiment by exchanging newborn rabbits between virus-infected and noninfected females. Two litters from virus-infected rabbits and one litter from a noninfected rabbit were all cannibalized after foster-nursing, however. We then examined whether newborn rabbits born to a virus-infected rabbit were already infected at birth with HTLV-I, but the virus could not be detected or isolated from cultures of their splenic lymphocytes. This is consistent with the absence of HTLV-I antigens in cord lymphocytes from neonates born to seropositive women.[4,6] Thus, milkborne rather than transplacental transmission of HTLV-I appears more likely. Previously, we demonstrated that only one of four adult rabbits could be infected with HTLV-I by twice-weekly oral inoculation of a large number of virus-infected cells.[10] Those results, compared with the present data, indicate that suckling rabbits may be more susceptible to oral transmission of HTLV-I.

HTLV-I is known to preferentially transform T cells from monkeys,[19] cats,[20] and rats,[21] as well as from humans.[13,22] Therefore, we wished to determine the lineage of the rabbit lymphoid cell lines transformed by this virus. Recently, monoclonal antibodies to rabbit T cells (L11/135)[15] and rabbit Ia antigens (2C4)[16] became available, and all four cell lines (Ra-7 to Ra-10) were reactive with both monoclonals in the absence of B cell markers. Thus, T cell tropism of HTLV-I appears to be a distinct feature common to a wide range of animal species.

ACKNOWLEDGMENT

We thank Dr J. M. Wilkinson for kindly providing L11/135 and 2C4.

CONCISE REPORT

Expression of the Macrophage-Specific Colony-Stimulating Factor in Human Monocytes Treated With Granulocyte-Macrophage Colony-Stimulating Factor

By Junko Horiguchi, M. Kim Warren, and Donald Kufe

The macrophage-specific colony-stimulating factor (CSF-1, M-CSF) regulates the survival, growth and differentiation of monocytes. We have recently demonstrated that phorbol ester induces expression of CSF-1 in human monocytes. These findings suggested that activated monocytes are capable of producing their own lineage-specific CSF. The present studies demonstrate that the granulocyte-macrophage colony-stimulating factor (GM-CSF) also induces CSF-1 transcripts in monocytes. Furthermore, we demonstrate that the detection of CSF-1 RNA in GM-CSF–treated monocytes is associated with synthesis of the CSF-1 gene product. The results thus suggest that GM-CSF may indirectly control specific monocyte functions through the regulation of CSF-1 production. These findings indicate another level of interaction between T cells and monocytes.

© 1987 by Grune & Stratton, Inc.

COLONY-STIMULATING FACTORS control the in vitro proliferation and differentiation of hematopoietic progenitor cells.[1,2] These factors include granulocyte/macrophage colony-stimulating factor (GM-CSF), granulocyte-CSF (G-CSF), macrophage-CSF (CSF-1, M-CSF) and multi-CSF (interleukin 3).[1] A cDNA for the T lymphocyte–derived GM-CSF has been cloned and recombinant GM-CSF protein purified to homogeneity.[2] This purified human GM-CSF has recently been shown to induce tumoricidal activity in human peripheral blood monocytes.[3] The effects of GM-CSF on specific gene expression in monocytes, particularly that of other CSFs, however, remains unclear.

CSF-1 is required for the survival, growth, and differentiation of monocytes.[4] The effects of CSF-1 are mediated by binding to the CSF-1 receptor, a 165-kd glycoprotein encoded by the c-*fms* protooncogene.[5] We[6] and others[7] previously demonstrated that the c-*fms* gene is expressed in cells differentiated along the monocytic lineage. More recent studies have demonstrated that CSF-1 is also expressed during phorbol ester–induced monocytic differentiation.[8,9] These findings suggested that monocytes may have the capacity to autostimulate certain functions through the production of CSF-1. Our previous studies, however, did not examine whether specific cytokines are capable of regulating CSF-1 expression in monocytes.

MATERIALS AND METHODS

Cell culture. Human peripheral blood monocytes were purified by Ficoll-Hypaque separation, adherence for one hour and then removal of the nonadherent cells.[10] The adherent cell population was collected with a plastic policeman, readhered overnight, and washed again with four changes of medium. The second adherent cell population consisted of over 98% monocytes by morphologic examination. Monocyte purification and culturing were performed in RPMI 1640 medium with 10% pooled human AB serum.[10] The purified monocytes were treated with 20, 100, 500, and 2,500 CFU-C/mL GM-CSF (specific activity: 5×10^4 CFU-C/μg).[2,3] The recombinant human GM-CSF was produced in yeast and was free of detectable endotoxin by the limulus assay.

DNA probes. The 1.6-kb fragment of a human CSF-1 cDNA was purified from the pcCSF-12 plasmid.[11] The 1.0-kb *Pst*I fragment of the v-*fms* gene was purified from the pSM3 plasmid.[6]

Hybridizations. The procedures used for RNA extraction, transfer, hybridization, and washing were as reported previously.[6]

CSF-1 determinations. The concentration of CSF-1 in tissue culture supernatants was determined by the CSF-1–specific radioimmune assay.[11]

RESULTS

We have previously shown that TPA treatment of human peripheral blood monocytes induces CSF-1 expression.[8] A maximum increase in CSF-1 RNA was achieved six hours after TPA induction and these transcripts declined thereafter. Treatment of resting human monocytes with GM-CSF similarly induced CSF-1 expression. The CSF-1 cDNA probe hybridized with a 4.6-kb transcript detectable at three hours of exposure to 500 CFU-C/mL GM-CSF (Fig 1). Similar findings have been obtained using poly A–selected monocyte RNA (data not shown). Furthermore, the level of CSF-1 RNA induced by GM-CSF remained detectable through 48 hours. In contrast, CSF-1 transcripts were undetectable following the same analysis of monocytes incubated in the absence of GM-CSF. The findings in GM-CSF–treated monocytes were also associated with a partial down-regulation of c-*fms* expression (Fig 1). Similar effects on CSF-1 and c-*fms* expression were obtained following treatment of monocytes with 20, 100, and 2,500 CFU-C/mL GM-CSF (data not shown).

We have also monitored production of the CSF-1 protein in GM-CSF–treated monocytes. CSF-1 levels in monocyte supernatants increased nearly tenfold at three hours of GM-CSF exposure (Fig 2). Furthermore, the CSF-1 levels remained elevated at 48 hours of treatment. In contrast, monocytes incubated in the absence of GM-CSF had no detectable supernatant CSF-1 at similar intervals and at 72 hours. Thus, CSF-1 expression at the RNA level corre-

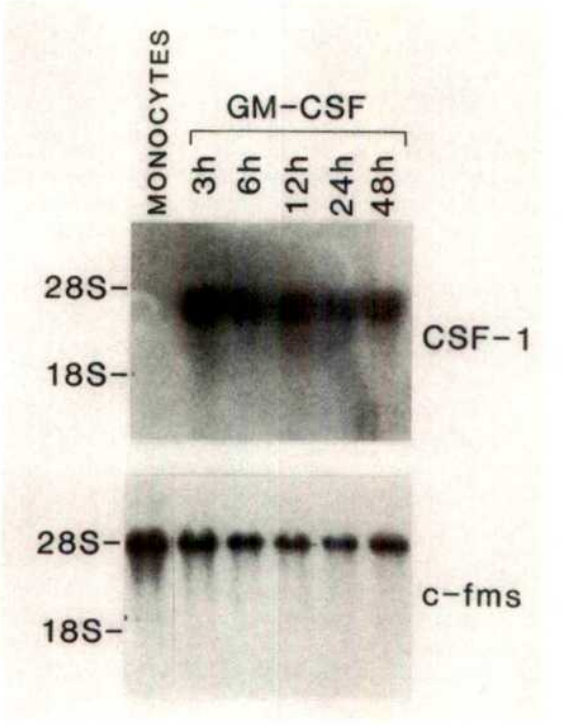

Fig 1. Levels of CSF-1 and c-*fms* RNA during treatment of human monocytes wity GM-CSF. Peripheral blood monocytes wre purified as described in Materials and Methods and treated with 500 CFU-C/mL GM-CSF. Total cellualr RNA was purified by the guanidine thiocyanate–cesium chloride method, analyzed by electrophoresis of 12 μg RNA through 1% agarose-formaldehyde gels followed by Northern blot transfer to nitrocellulose. The RNA filters were hybridized to the ^{32}P-labeled nick-translated CSF-1 and v-*fms* probes.

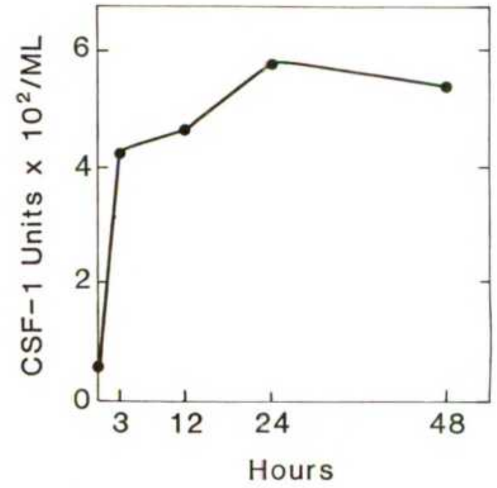

Fig 2. CSF-1 levels in tissue culture supernatants of GM-CSF treated monocytes. Monocytes were treated with GM-CSF as described in the legend to Fig 1. The supernatants were assayed for CSF-1 using the CSF-1-specific radioimmune assay.[11] The values represent the CSF-1 concentration for 1×10^8 monocytes/mL. The value shown for the zero time point represents the lower limit of this assay.

sponded with detection of the CSF-1 protein in culture supernatants.

DISCUSSION

The present results demonstrate that GM-CSF induces CSF-1 expression in human monocytes. This induction occurred during the continued expression of c-*fms* transcripts. Since c-*fms* encodes for the CSF-1 receptor, the findings would suggest that GM-CSF treated monocytes may regulate their own growth and differentiation through CSF-1 production. Thus, the in vitro effects of GM-CSF on macrophage colony formation[1] may be mediated in part by induction of CSF-1 expression. Furthermore, recent studies have demonstrated that CSF-1 also stimulates human monocyte production of interferon, tumor necrosis factor, and myeloid colony-stimulating activity.[12] Taken together, these findings would suggest that GM-CSF, and therefore T lymphocytes, may indirectly control specific functions of monocytes through the regulation of CSF-1 expression.

Other cytokines appear capable of inducing CSF-1 in monocytes. Previous studies have demonstrated that T cell–derived gamma-interferon induces release of monocyte colony-stimulating activity from purified human monocytes.[9,13] Thus, gamma-interferon and GM-CSF may both contribute to the interaction between T cells and monocytes by inducing CSF-1 expression. Furthermore, our studies have not addressed the possibility that GM-CSF first induces expression of a monokine, which in turn regulates CSF-1 production. In this regard, recent studies have demonstrated that both tumor necrosis factor and interleukin 1 are capable of stimulating monocyte cytotoxicity.[14] The effects of these monokines on CSF-1 expression in human monocytes will require further study.

ACKNOWLEDGMENT

The authors thank Dr Steven Gillis, Immunex Corporation, for providing the purified recombinant GM-CSF.

CONCISE REPORT

Bone Marrow Transplantation in Multiple Myeloma: Report From the European Cooperative Group for Bone Marrow Transplantation

By G. Gahrton, S. Tura, M. Flesch, A. Gratwohl, P. Gravett, G. Lucarelli, M. Michallet, J. Reiffers, O. Ringdén, M.T. van Lint, J.P. Vernant, and F.E. Zwaan

Of 14 patients who received an allogeneic bone marrow graft from HLA-compatible sibling donors, 10 have survived for 6 to 34 months posttransplantation (median, 12 months). Four patients have died, two of relapse at extramedullary sites, one of severe acute GVHD, and one from GI bleeding and pericardial effusion. One patient is alive in relapse and four patients have signs of minimal persistent disease. Five patients are well without signs of active disease. Minor improvement in osteolytic lesions on X-ray were seen in three patients, but the X-ray bone structure was mainly unchanged in most patients. Bone marrow transplantation appears promising for treatment of certain patients with multiple myeloma.

© 1987 by Grune & Stratton, Inc.

ALLOGENEIC BONE MARROW transplantation (BMT) has proved to be an efficient method for treatment of patients with a variety of hematological malignancies, in particular acute leukemia and chronic myelocytic leukemia.[1] BMT has also been performed in a few patients with multiple myeloma,[2-6] three of whom have survived more than two years posttransplantation, although they were transplanted in an advanced stage of the disease. Within the European Cooperative Group for Bone Marrow Transplantation (EBMT), 14 myeloma patients have been transplanted. This report describes the outcome for these 14 patients, some of whom have been presented previously in preliminary reports.[5-6]

MATERIALS AND METHODS

Fourteen patients (8 women, 6 men, median age 35 years) (Table 1) were reported to the EBMT registry, having been transplanted for multiple myeloma. All patients had been treated with cytotoxic drugs prior to BMT. Five were in stage III, two in stage II, and seven in stage I prior to the start of consolidation treatment. Five were considered refractory to treatment (patients 4, 6, 7, 8, and 10), while 9 were not refractory to first- or second-line treatment. Five patients had received only melphalan and prednisolone before transplant; two of them were refractory to this treatment, and two were responding. Nine patients had received a combination of various cytotoxic drugs. The time from diagnosis to BMT varied considerably (median 14 months).

All patients were conditioned before BMT with both cyclophosphamide and total body irradiation (modified Seattle protocol).[7] Five patients received additional cytotoxic drugs, ie, CCNU (lomustine), BCNU (carmustine), vincristine, prednisolone, and melphalan in variable regimens. Eight patients received total body irradiation in a single dose and six in fractions over three to five days. The total dose varied between 9.5 and 12 Gy, according to whether it was given as a single dose or in fractions.

All patients were advised of BMT procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent.

RESULTS

Of the 14 patients, 10 are alive 6 to 34 months (median 12 months) post-BMT (Table 1). Four patients died ½ to 4½ months posttransplant. One patient with an IgG-lambda plasma-cell leukemia died with a meningeal relapse 4½ months post-BMT, and one patient with an IgG-kappa myeloma died with a cerebral relapse. In these two patients there were no signs of generalized disease. One patient died from GI bleeding and pericardial effusion, and the fourth patient died of severe GVHD.

Among the surviving patients five were well and without signs of disease. Two of them were considered refractory to the chemotherapy before BMT. They had no abnormal serum immunoglobulins, light chains in the urine, or abnormal plasma cells in the marrow at reporting. Four patients had persistent minimal signs of disease (patients 3, 4, 10, and 14) (Table 1) and one patient relapsed (patient 5).

The pretransplant bone structure on X-ray was only moderately changed posttransplantation. Of the five patients without signs of active disease in serum, urine or bone marrow post-BMT, three had advanced lytic lesions before transplant. After BMT no clear change was observed in one of these patients, while two were rated as having only minor lytic lesions. In the other two patients no change in the bone structure was observed posttransplant (normal bone structure and minor bone lesions, respectively). Of the four patients with minimal disease, two were rated as having

*Earlier reported after shorter follow-up time (5,6) minor bone lesions before BMT. In one of these patients there was no change; the other had normal bone structure at reporting. Two patients had normal bone structure before transplant. In one there is still no change, while one now has minor bone lesions.

Only one patient had severe (grade IV) acute GVHD (patient 13). No patient had severe chronic GVHD, and four had mild chronic GVHD.

DISCUSSION

This report shows that bone marrow transplantation can be successful in patients with multiple myeloma. Five of 14 patients are well without signs of active disease 9 to 34 months posttransplantation. Four other patients are well with only minimal changes in either serum Ig, urinary light chains, or bone marrow plasma cells, indicating persistent disease. Although the observation time is short (median 12 months for surviving patients), only three patients have relapsed. The nature of minimal persistent disease is uncertain, and these patients may well relapse later. In fact, patient 5 had signs of persistent disease for some months before relapse at 11 months post-BMT. On the other hand, the four patients with persistent minimal disease at reporting have now survived for 6, 8, 12, and 13½ months without progressing. It is possible that these minimal changes may disappear, perhaps due to a graft-versus-myeloma effect as previously described for acute leukemia.[8] The significance of persistent bone lesions on X-ray is difficult to judge. Three of five patients who were well without signs of active disease at this report had advanced osteolytic lesions at transplant. Although one still has advanced osteolytic lesions and the other two minor ones, none has signs of active disease 9 to 12 months post-BMT. One patient who had minor osteolytic lesions unchanged post-transplant has now survived for 34 months. Thus, persistent osteolytic lesions may not indicate a risk for relapse.

Side effects of BMT in this material were in general not different from those described previously.[1] It is of interest to note, however, that only one patient had severe acute GVHD (T cell–depleted) and none had severe chronic GVHD. Thus, despite the relatively advanced age of the patients, GVHD was a minor problem.

The optimal time for transplantation of patients with multiple myeloma cannot be judged from the present report. However, it seems reasonable to transplant patients with an HLA-compatible sibling donor if the prognosis is poor with current chemotherapy. Recently some prognostic factors have been delineated,[9] ie, patients with a rapid response to treatment, with IgD myeloma, and with a high thymidine-incorporation labeling index appear to have a relatively poor prognosis. These patients could perhaps be transplanted at an early stage of the disease. Also, since two out of five patients considered refractory to chemotherapy were without signs of active disease 9 and 34 months post-BMT, patients that are resistant to first-line treatment may well be successfully transplanted before second-line treatment is instituted.

APPENDIX

This study was based on reports from the following centers within the European Cooperative Group for Bone Marrow Transplantation (EBMT): Huddinge Hospital, Huddinge, Sweden (G. Gahrton, O. Ringdén, B. Lönnqvist, and P. Ljungman), University Hospital, Bologna, Italy (S. Tura), Hospital Jean-Minjoz, Besancon, France (M. Flesch), Cromwell Hospital, London, UK (P.J. Gravett and D. Guéret-Wardle), Pesaro Hospital, Pesaro, Italy (G. Lucarelli), University Hospital, Grenoble, France (M. Michallet, B. Corront, and D. Hollard) University Hospital, Pessac, France (J. Reiffers, G. Marit, and B. David) Hospital S Martin, Genova, Italy (M.T. van Lint), and University Hospital, Creteil, France (J.P. Vernant).

CONCISE REPORT

Monocyte Adhesion to Subendothelial Components

By John W. Tobias, Murray M. Bern, Peter A. Netland, and Bruce R. Zetter

Human monocytes have been shown to penetrate the endothelial layer of large blood vessels and to adhere to the subendothelial basement membrane. To determine the active components of this process, we have studied the ability of monocytes to adhere to isolated components of the subendothelial matrix. Using a quantitative dot-blot adhesion assay, we find that monocytes adhere preferentially to immobilized laminin and elastin. The monocytes adhere less well to fibronectin and bind poorly or not at all to collagen types I and IV, or to heparan sulfate. Monocyte binding to elastin requires an intact, crosslinked molecule as no binding was observed to soluble, acid-alcohol elastin extracts, to pepsin or elastase digests of elastin, to tropoelastin monomer, or to desmosine/isodesmosine crosslinks. Similar binding profiles to elastin, laminin, and fibronectin were seen with the established human leukocyte cell line U937. The promyelocytic cell line HL60 adhered equally well to laminin but showed slightly reduced adhesion to elastin when compared with the fresh monocytes or U937 cells. Freshly isolated human erythrocytes did not demonstrate significant adhesion to fibronectin, laminin, or elastin.

© 1987 by Grune & Stratton, Inc.

IT HAS RECENTLY BEEN demonstrated that blood-borne mononuclear cells can penetrate the vascular endothelium in large blood vessels and adhere to the subendothelial basal lamina.[1-3] It has been suggested that these monocytes are the precursors of the lipid-laden foam cells associated with atherosclerotic lesions.[4,5] Monocyte-derived growth factors may also mediate the smooth muscle cell migration and proliferation that is an early step in the pathogenesis of atherosclerosis.[6,7]

The molecules that mediate monocyte adhesion to the subendothelial extracellular matrix have not yet been determined. It is possible that there are multiple determinants in the extracellular matrix (ECM) to which monocytes can adhere. To explore this question, we have tested several known components of the vascular ECM for their ability to bind monocytes. Our results demonstrate that monocytes and related leukocyte cell lines adhere preferentially to laminin and elastin. The cells adhere less well to fibronectin and do not bind appreciably to other matrix components.

MATERIALS AND METHODS

Isolation of human peripheral blood monocytes. Whole blood from a fasting donor was collected in Vacutainer tubes (Becton Dickinson, Rutherford, NJ) containing 0.1 mL of 15% ethylenediaminetetraacetic acid. One mL of 6.0% Dextran T500 (Pharmacia Fine Chemicals, Piscataway, NJ) in Ca++- and Mg++-free phosphate buffered saline (PBS, GIBCO, Grand Island, NY) was added to every 9 mL of whole blood. After the erythrocytes had been allowed to settle for 35 to 45 minutes at room temperature, the leukocyte-rich plasma was removed and layered in 6-mL aliquots over 3 mL of Nycodenz (Accurate Chemical & Scientific, Westbury, NY) adjusted with 1.02% NaCl to a final density of 1.067 g/mL and an osmolarity of 330 mosmol/L according to the method of Bøyum.[8] After centrifugation at 2,000 × g for 15 minutes, the interface and the upper 1 mL of the bottom layer were collected. Approximately 2×10^5 mononuclear white blood cells were obtained per mL of whole blood. The collected cells were shown to be >92% monocytes by the criteria of morphology and nonspecific esterase activity.[9] In some experiments, erythrocytes were collected from the same blood samples.

Other leukocyte cell lines. U937 cells, a human lymphoma-derived cell line with monocytelike properties[10] and HL60, a human promyelocytic cell line[11-14] were generously provided by Dr Michael Bevilacqua, Brigham and Women's Hospital, Boston, MA. Both cell lines were grown in suspension culture in RPMI 1640 medium supplemented with 10% fetal calf serum (GIBCO).

Cellular radiolabeling. Cells were suspended at a concentration of 2×10^6 cells/mL in PBS containing 0.5% bovine serum albumin (Boehringer Mannheim, Indianapolis, IN) and 200 μCi/mL sodium ^{51}chromate (Dupont–New England Nuclear, Boston, MA). The suspension was incubated for one hour at 37°C with occasional stirring. The suspension was then brought to a volume of 10 mL in Ca++- and Mg++-free PBS and centrifuged at 800 × g for 10 minutes. The pellet was washed twice in 10 mL PBS and brought to a final concentration of 2×10^5 cells/mL in HEPES-buffered Medium 199 (GIBCO) and an aliquot was counted in a Beckman (Irvine, CA) 5500 gamma counter. The labeled cells had an average activity of 0.09 to 0.16 dpm/cell.

Adhesion assay. The cell adhesion assay employed in these studies was performed as previously described.[15] Briefly, adhesion molecules were adsorbed under vacuum to 4-mm dots on Zeta-Probe nylon membranes (Bio-Rad, Richmond, CA) in a Schleicher and Schuell (Keene, NH) "Minifold" apparatus. The nylon membrane was removed from the Minifold and cut into squares containing four dots per square. These squares were then placed into individual wells of a Costar 12-well culture dish (Bellco Glassware, Vineland, NJ) and incubated at 37°C for 18 hours in PBS containing 0.5% bovine hemoglobin (Sigma, St Louis) to block sites on the membrane not occupied by the test molecule. The membranes were then washed twice with hemoglobin-free PBS and once with Medium H-199. Each well then received 2 mL of serum-free medium H-199 containing 2×10^5 cells/mL. They were then incubated for 25 minutes at 37°C on a rotary shaker rotating at 50 rpm (American Rotator V.

0006-4971/87/6904-0050$3.00/0

American Scientific Products, Miami, FL). After the incubation, the membranes were washed twice gently in 4°C PBS to remove unbound monocytes and then fixed in 1.0% glutaraldehyde (Eastman, Rochester, NY) for 30 minutes at room temperature. The membranes were finally rinsed twice in PBS and dried overnight in a vacuum desiccator. Binding of the monocytes was visualized by exposing the membranes to Kodak XAR-5 X-ray film for two to three days at −20°C (Fig 1B). Binding was quantified by punching out the individual dots and counting the associated radioactivity.

Reagents. Mouse lung elastin was purified in our laboratory according to the method of Barnard et al.[16] Bovine aortic elastin, purified according to the Starcher method[17] was obtained from Elastin Products Company (EPC, Pacific, MO). Amino acid analysis of the elastin preparations, performed by Dr David Ander, Harvard Microchemistry Facility, Cambridge, MA,[15] yielded profiles consistent with that of purified elastin according to the criteria of Soskel and Sandberg.[18] Alpha, kappa and kappa-2 elastin hydrolysates as well as desmosine/isodesmosine were from EPC. Tropoelastin monomer was purified from neonatal rat aortic arch smooth muscle cells according to the method of Sandberg as modified by Chipman et al.[19] Collagen types I and IV were generously provided by Dr Helene Sage, University of Washington, Seattle, WA. Samples of laminin and fibronectin were gifts of Dr Donald Ingber, Children's Hospital, Boston, MA. Chondroitin sulfate was from Sigma. Heparan sulfate was from Diosynth, Chicago, IL.

RESULTS

Isolated components of the subendothelial extracellular matrix were adsorbed to 4-mm dots of nylon-based membrane and tested for their ability to mediate monocyte attachment. When blocked with BSA or hemoglobin, the membrane itself had no significant monocyte binding activity. Monocytes did, however, adhere to elastin or laminin that had been adsorbed onto the nylon membranes (Fig 1). The binding to each of the two molecules was dose-dependent and did not saturate at doses below 100 μg/dot. Fewer monocytes bound to membranes containing 75 μg/dot fibronectin than to equivalent doses of laminin or elastin. Other ECM components were tested for their ability to mediate monocyte adhesion. No adhesion activity was seen with heparan sulfate, chondroitin sulfate, or with collagen types I or IV (Fig 2). Control experiments with ^{3}H-elastin, laminin, and fibronectin that had been labeled by reductive methylation with sodium borohydride[20] revealed no significant difference in the binding of any of these factors to the nylon membrane (not shown). In each case, greater than 90% of the molecules bound at all doses below 100 μg/dot. Above this concentration, the membranes became saturated and binding was variable.

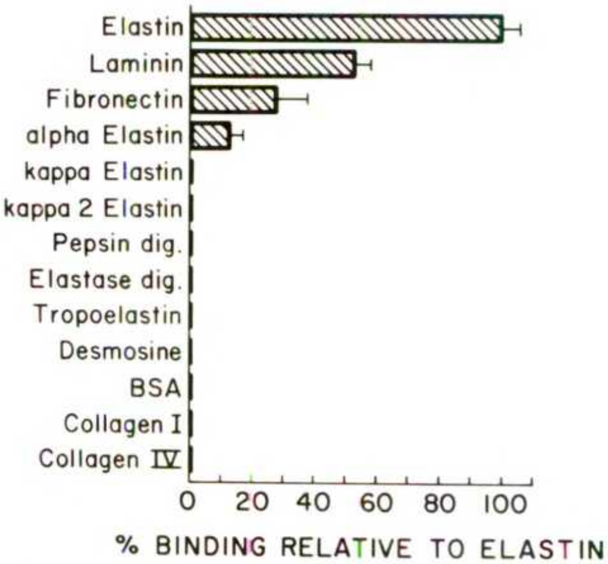

Fig 2. Comparative binding of human peripheral monocytes to extracellular matrix components. Seventy-five μg of each molecule was adsorbed to 4-mm dots on nylon membranes and the membranes were then incubated with radiolabeled monocytes. Data are expressed as the percent binding relative to elastin (mean ± SD, N = 4).

In situ, elastin exists as a hydrophobic, highly crosslinked, insoluble molecule.[21,22] To determine whether the structure of mature crosslinked elastin was required for its adhesive properties, we tested several preparations of solubilized elastin for their adhesive potential. No significant activity was observed with hydrolysates of elastin that had been prepared by incubating bovine aortic elastin with pepsin or with pancreatic elastase or by treatment with acid to make alpha elastin[23] or with alkali to make kappa or kappa-2 elastin.[24] Monocytes also failed to adhere to tropoelastin monomer isolated from newborn rat aortic arches. Finally, no adhesion was observed to desmosine/isodesmosine, a synthetic preparation of the crosslinking region specific to elastin.[25] Together, these results suggest that the adhesive activity of the mature elastin molecule is dependent on an intact cross-linked molecule and cannot be duplicated by tropoelastin or by hydrolytic fragments of the parent molecule.

Two established human cell lines were also tested for their ability to bind to extracellular matrix components: U937 cells originally derived from a diffuse histiocytic lymphoma[10]

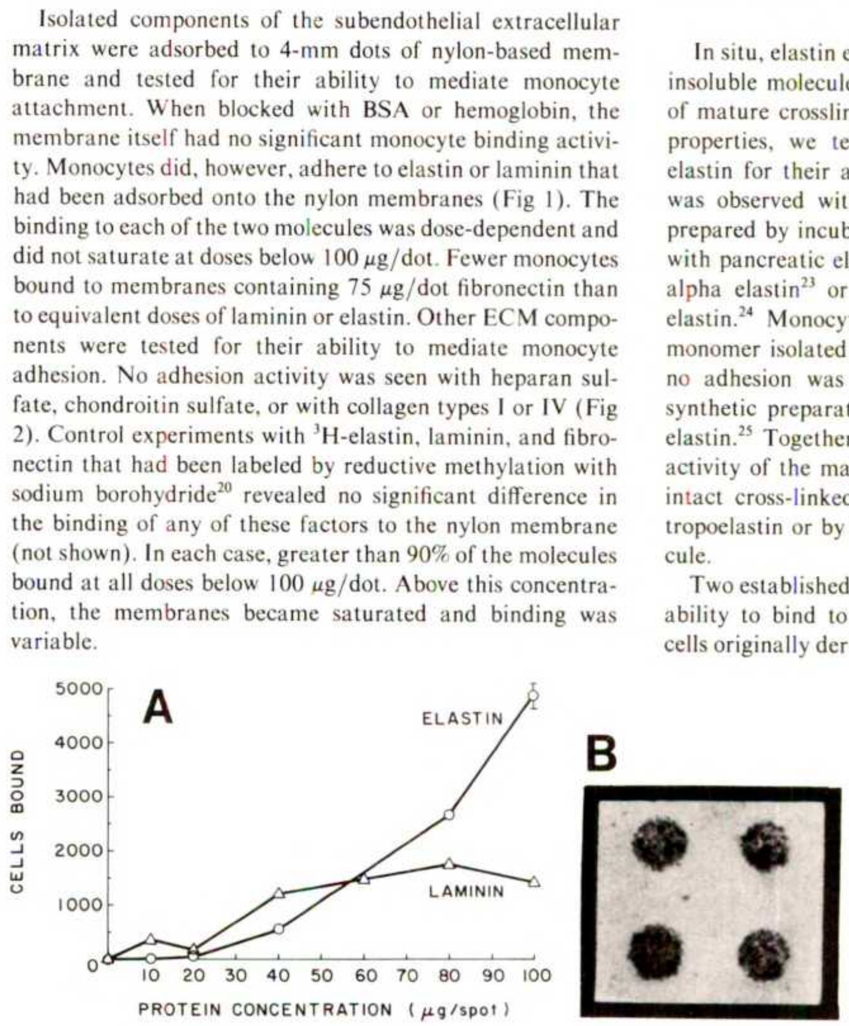

Fig 1. (A) Dose response of monocyte binding to laminin and elastin. Elastin and laminin were adsorbed at the indicated concentrations to 4-mm dots on nylon membranes. After incubation with radiolabeled cells, the number of adherent cells was measured as a function of the radioactivity associated with each dot. Data points represent the mean of four separate determinations. (B) Autoradiography of dots with adherent monocytes.

and the promyelocyte cell line HL60.[11-14] The monocytelike U937 cells have a binding affinity nearly identical to that of the freshly isolated monocytes with maximal binding to elastin followed by laminin and fibronectin (Fig 3). The HL60 cells also bound to these three molecules showing slightly greater adhesiveness to fibronectin and slightly reduced adhesiveness to elastin when compared with the freshly isolated monocytes or the U937 cells. Human erythrocytes, in contrast, failed to show significant binding to elastin, laminin, or fibronectin.

DISCUSSION

Components of the vascular extracellular matrix have been shown to be adhesion molecules for a variety of cell types.[26,27] Because of recent interest in the adhesion of monocytes to the subendothelial vascular basement membrane,[2] we attempted to elucidate the nature of the cell adhesion molecules in the vessel wall that mediate monocyte adhesion. Our results demonstrate that freshly isolated human peripheral blood monocytes adhere strongly to laminin and elastin. Fibronectin was a less effective monocyte adhesin, and neither heparan sulfate, nor collagen types I and IV had appreciable activity. An established human cell line with monocytelike properties (U937) and a human promyelocytic cell line (HL60) had similar adhesive specificities, whereas human erythrocytes failed to bind markedly to either elastin, laminin, or fibronectin.

It has been shown previously that mononuclear cells interact with elastin. Monocytes release a proteolytic enzyme that has potent elastolytic activity.[28,29] Furthermore, the elastin fragments produced by proteolytic cleavage of mature elastin have chemotactic activity for monocytes.[30] It has been postulated that these activities allow monocytes to invade and migrate across the elastic components of blood vessels in the process of inflammatory extravasation. To these interactions we now add a third, the adhesion of monocytes to intact elastin.

Monocytes bind to elastin in a dose-dependent fashion. No adhesive activity is associated with soluble noncrosslinked tropoelastin monomer or with fragments of elastin produced by protease digestion or by extraction in acid or alkali even though such fragments have ample chemotactic activity.[30] The mechanism by which monocytes adhere to mature crosslinked elastin but not to elastin fragments or elastin monomer is not yet known.

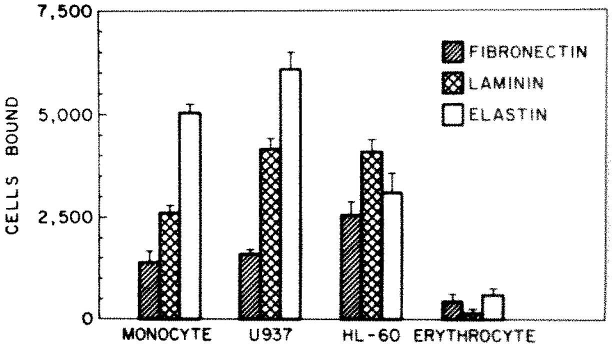

Fig 3. Comparative binding of human peripheral monocytes, U937 cells, HL60 cells, and erythrocytes to elastin, laminin, and fibronectin. Radiolabeled monocytes, U937 cells, HL60 cells, and human erythrocytes were incubated for 25 minutes at 37°C with nylon membranes containing 75 μg/dot elastin, laminin, or fibronectin. Background binding to untreated membranes was subtracted for each cell type. Data represent the number of cells bound per 4-mm dot (mean ± SD, n = 4).

Monocyte adhesion to the subendothelial basal lamina has been proposed to play a role in the pathogenesis of atherosclerosis.[1,2] These monocytes may be precursors of the lipid-laden foam cells characteristic of atherosclerotic lesions.[3,4] Both elastin and laminin are major components of this basal lamina and are well situated to mediate monocyte attachment. Laminin has also been shown to be chemotactic for tumor cells,[31] but its ability to mediate monocyte motility has not yet been determined. One question that remains to be answered is why the monocytes do not penetrate farther into the vascular wall, since they release enzymes that degrade basement membrane components and can migrate in response to those degradation products. Further studies on the regulation of adhesion, proteolytic enzyme production, and cell motility should provide new insights into monocyte participation in vascular disease processes.

ACKNOWLEDGMENT

We thank Dr Michael Bevilacqua, Brigham and Women's Hospital, Boston, MA for providing the human monocytelike cell lines and Dr Stuart Chipman, Children's Hospital, Boston, MA for advice and assistance in the preparation of tropoelastin monomer.

CORRESPONDENCE

IMMUNE LYMPHOCYTE SURVIVAL AFTER CHEMOTHERAPY AND RADIATION

To the Editor:

This letter is in reply to a concise report recently published in *Blood.*[1] We would like to add our own evidence that immune lymphocytes survive after high-dose cyclophosphamide (60 mg/kg) body weight/day × 2 days), arabinosyl cytosine (3 g/m^2 body surface × 2, 12 hours apart), and total body irradiation (1,200 rad in 3 days). We analyzed the phenotype of cells removed by lymphocytapheresis in five patients just prior to infusion of donor marrow and found 55% $T3^+$, 45% $T4^+$, 22% $T8^+$, 27% $T10^+$, 17% Leu 11^+, 26% $M1^+$, and 4% $M3^+$ cells (mean values). To test the functional ability of these cells, we stimulated them with phytohemagglutinin and Daudi cells for 48 hours and then assayed for interleukin-2 (IL 2) activity. These cells, after high-dose chemotherapy and irradiation, produced 1.5 times the amount of IL 2 generated by untreated, normal lymphocytes in the same way. Similarly, we noted high IL 2 activity in lymphocytes of patients with head and neck cancer after irradiation.

Malkovsky and Medawar[2] propose that IL 2 is the determining factor in whether tolerance or T cell reactivity follows an immunological encounter. Antigen exposure in the absence of IL 2 results in tolerance. Our experience is in agreement with this. In 14 patients who were lymphocytapheresed just prior to donor marrow infusion (after pretransplant conditioning), graft *v* host disease (GVHD) developed in only 2 (14%) and a mild generalized maculopapular rash developed in only 1. Furthermore, if the natural killer (NK) cells we found in the host are functional and their activity is enhanced by IL 2 as suggested by Domzig and co-workers,[3] theoretically they could be responsible for the graft rejection that occurs in some patients.

ANNOUNCEMENTS

DR H. DUBOIS-FERRIÈRE—DINU LIPATTI RESEARCH FELLOWSHIP IN HEMATOLOGY

The Dr H. Dubois-Ferrière—Dinu Lipatti Foundation offers a research fellowship to a medical graduate with at least two years' experience in research. The recipient of the fellowship will have the opportunity to spend two or three years working on a hematology research program in Geneva. The annual stipend ranges from US $30,000 to $35,000.

For further information, contact: Fondation Dr H. Dubois-Ferrière—Dinu Lipatti, case postale 225, CH-1227 Carouge-Genève, Switzerland.

TENTH INTERNATIONAL CONGRESS OF PHARMACOLOGY

August 23-28, 1987
Sydney, Australia

For further information, contact: the Secretariat, Tenth IUPHAR Congress, GPO Box 2609, Sydney, NSW, Australia. Telephone: (+61) (02) 241 1478. Telex: AA 74845 CONSEC. Cables: CONVENTION Sydney. Further information may also be obtained through your national pharmacology society.

SECOND INTERNATIONAL CONFERENCE ON THALASSEMIA AND THE HEMOGLOBINOPATHIES

October 21-24, 1987
Herakleion, Crete, Greece

The Conference aims to unite the Third Mediterranean Meeting on Thalassemia and the respective meetings of the AMEDETH (*Association Mediterraneenne pour l'etude, le depistage et le traitement des hemoglobinoses*) and the *Club de l'hemoglobine* in an effort to avoid repetition, upgrade the level of presentations, promote collaboration, and save time and expenses. The scientific program will include lectures, round table discussions, and poster sessions covering the field of thalassemia, namely its molecular biology, therapeutic modalities, and evaluation, as well as prevention and social aspects. The Conference will be preceded by a training seminar. Crete is an ideal place for the Conference at this time of the year: the weather is pleasant and warm and the island is full of natural beauty and archaeological sites of utmost interest.

For further information, please write to the 2nd International Conference on Thalassemia and the Hemoglobinopathies, Secretariat, First Department of Medicine, University of Athens, PO Box 14 173, 115 10 Athens, Greece.

NATIONAL BLOOD CLUB
IRON METABOLISM: NEW INSIGHTS THROUGH MOLECULAR BIOLOGY

Saturday, May 2, 1987 8:00-10:30 PM
California Room, Conference Center, Town and Country Hotel, San Diego, CA

"Ferritin Genes"
Richard Klausner, MD, National Institutes of Health
"Ribonucleotide Reductase"
David Martin, PhD, Genentech, Inc
"The Atransferrinemic Mouse"
Jerry Kaplan, PhD, University of Utah

FOURTH INTERNATIONAL WORKSHOP AND CONFERENCE ON HUMAN LEUKOCYTE DIFFERENTIATION ANTIGENS

1989
Vienna

The aim of this workshop series is to exchange antihuman leukocyte monoclonal antibodies among laboratories, to characterize and compare the nature of the antigens identified, to analyze the data centrally, and to publish the results jointly. The preparations for the wet workshop part, which will be followed by a joint conference in Vienna, are now beginning. The workshop will be organized into six sections: T cells, B cells, NK cells, myeloid cells, platelet antigens, and activation antigens.

Those who are interested in submitting monoclonal antibodies and/or receiving certain antibodies for in-depth evaluation are requested to write at their earliest convenience to: Fourth International Workshop on Human Leukocyte Differentiation Antigens, Attn. W. Knapp, Institute of Immunology, University of Vienna, Borschkegasse 8a, A-1090 Vienna, Austria.

AN OPEN INTERNATIONAL DISCUSSION SYMPOSIUM "NEWER STRATEGIES IN THE MANAGEMENT OF THROMBOTIC DISORDERS"

November 12-14, 1987
Loyola University Medical Center, Maywood, IL

DISCUSSANTS (PROPOSED)

Topics: heparin and its derivatives; Ticlopidine—newer antiplatelet drugs; T-PA and related thrombolytic agents; Defibrotide and related drugs; viscosity modulators; biotechnology-based products; polytherapy of thrombotic disorders; mechanical devices; physical devices; and target-specific agents.

This is an open symposium and all interested individuals are invited to attend. The program will be available in October and will be forwarded to those interested via circulars. No registration fee is required from the participants; however, the registration is limited to the first 200. *For further information, contact:* Dr J. Fareed, Loyola University Medical Center, 2160 S First Ave, Maywood, IL 60153. Telephone: (312) 531-3256.

INTERNATIONAL SOCIETY OF HEMATOLOGY SIXTH INTERNATIONAL CONGRESS OF THE ASIA-PACIFIC DIVISION

December 6-10, 1987

Extensive arrangements are being made by the Host Committee for a special package combining the business meetings and a short escorted tour for ASH members and their families. A brochure including details of the program, the registration form and reply card, and additional information has been mailed to all ASH members. Interested persons may register early with no obligation. Representatives of companies interested in advertising in the special issue of the brochure or in holding displays at the World Congress Booth are encouraged to contact the Program Coordinator.

For further information or registration, contact: Aloke C. Bagchi, Official Program Coordinator, 6101 N Talman Ave, Chicago, IL 60659-0577. Telephone (312) 465-8337.

ERRATA

In the article by Graf and Pesando entitled "Evidence for Chemical Differences in HLA-DR Molecules on Autologous Acute Lymphoblastic Leukemia and B-Lymphoblastoid Cell Lines," which appeared in the January 1987 issue (Volume 69, pp 7-11), the bottom of Figure 7 is not shown. Figure 7 is reprinted in its entirety below.

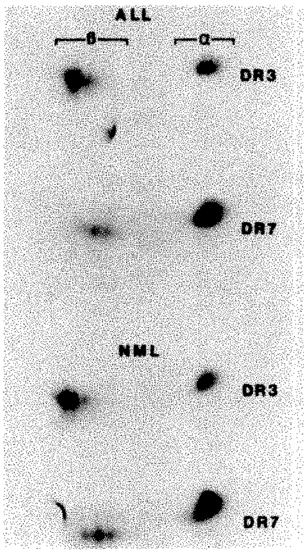

Fig 7. Two-dimensional gel electrophoresis of neuraminidase treated HLA-DR molecules from NALM-6 (ALL) and B85 (NML) cells. The HLA-DR3-specific MoAb I-2 and the HLA-DR7–specific MoAb SFR16-DR7M were used to study both of these cell lines. All four samples were compared simultaneously as in Fig 6.

In the article by Sorette et al entitled "Ektacytometric Measurement of Sickle Cell Deformability as a Continuous Function of Oxygen Tension," which appeared in the January 1987 issue (Volume 69, pp 316-323), the legends for Figures 3-6 were transposed and text citations of those Figures were misnumbered. The following two pages show Figures 3-6 with the correct legends and text citations. Address requests for corrected reprints to Margaret R. Clark, PhD, Box 0128, Cancer Research Institute, University of California, San Francisco, CA 94143.

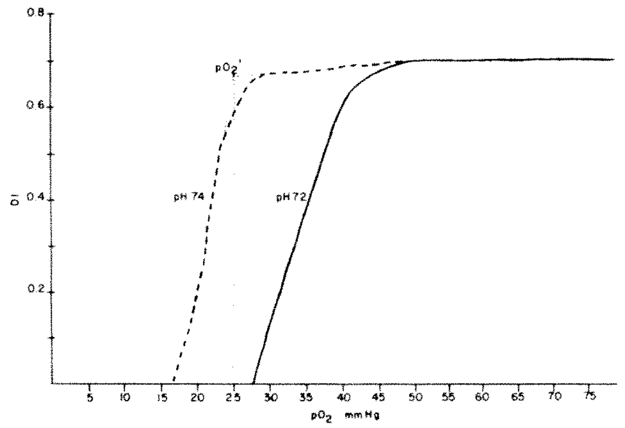

Fig 2. Variation in deformability signal (DI) as a function of oxygen tension for a Fraction 2 gradient population. As shown here, cell deformability decreased abruptly over a relatively narrow range in pO_2, producing a curve that essentially represented two intersecting lines. The point of intersection was used to define the pO_2 at which loss of deformability was first detected (pO_2'). Reduction of the pH from 7.4 to 7.2 shifted this critical pO_2 to higher values, reflecting the pH-induced increase in HbS polymerization.

down to a critical pO_2 level, after which it decreased in essentially linear fashion. Thus, the intersection of the two linear portions of the curve was used to identify the pO_2 value at which a loss of deformability was first detectable (designated pO_2' in Fig 2). In addition, because this value was expected to vary with MCHC, we also used the pO_2 at which the DI fell to a value of 0.2 to characterize each curve. The data shown in this figure and in Figs 4 through 6 were obtained on cell populations collected from the interface between the first and second layers of Stractan (Fraction 2). Such density-separated cell populations displayed a sharper transition in deformability with oxygen tension than whole blood, as expected from their greater homogeneity (data not shown). It can be seen that these Fraction 2 samples in the various experiments did not give identical DI *v* pO_2 curves. Comparison of the oxygen dissociation curves for the samples showed that differences in oxygen affinity, presumably due to individual patient differences and differences in cell storage time, were the major source of variation.

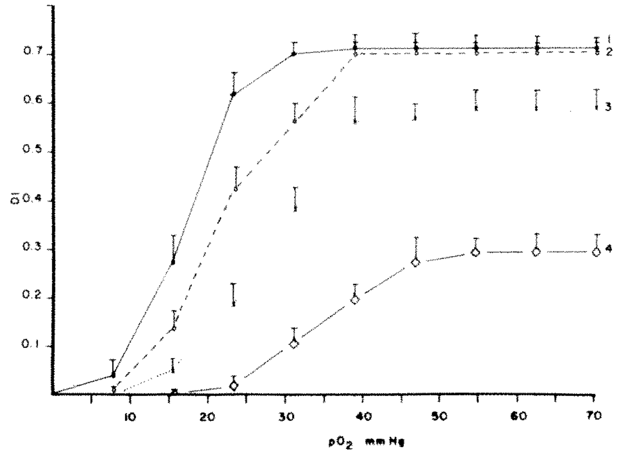

Fig 3. DI *v* pO_2 curves for Fractions 1 to 4 of Stractan-separated sickle cells. As the MCHC of isolated cell populations increased, the maximum DI decreased, and a deoxygenation-dependent loss in cell deformability occurred at progressively higher pO_2. See Table I for characteristics of the cell populations.

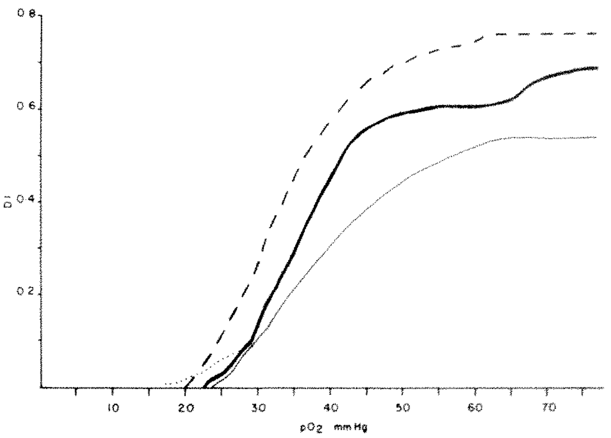

Fig 4. Effect of suspending medium viscosity on the DI *v* pO_2 curve for a Fraction 2 gradient population. A decrease in viscosity below 19.5 cp at 37 °C cp (4% PVP concentration) resulted in overall reduction in cell deformation and eventual blurring of the deoxygenation-dependent loss of cell deformability. (-----) 19.5 cp, (——) 12.5 cp, (——) 9.5 cp, (·····) 7.5 cp.

A series of experiments was performed to determine the effect of important experimental variables and to define the optimal procedure to obtain reproducible, physiologically relevant data. As expected from the characteristics of the polymer equilibrium, several factors predictably affected the range of oxygen tension over which the cell deformability loss occurred. Reduction of the suspending medium pH from 7.4 to 7.2 caused a parallel shift of the DI *v* pO_2 curve to higher pO_2 (Fig 2), consistent with the increased Bohr effect of HbS, particularly below an extracellular pH of 7.4, and the corresponding enhancement of polymer formation.[4,20] Most of the experiments employed paired deformability and oxy-

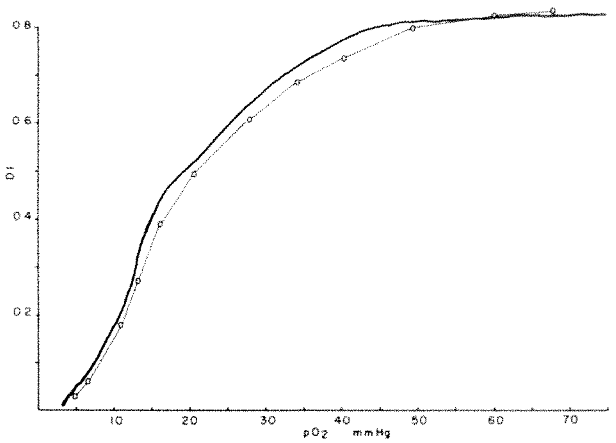

Fig 5. Comparison of DI *v* pO_2 relationship for continuous pO_2 gradient (continuous curve) and for measurements performed at fixed pO_2 values (open circles) over the same range for a Fraction 2 gradient population.

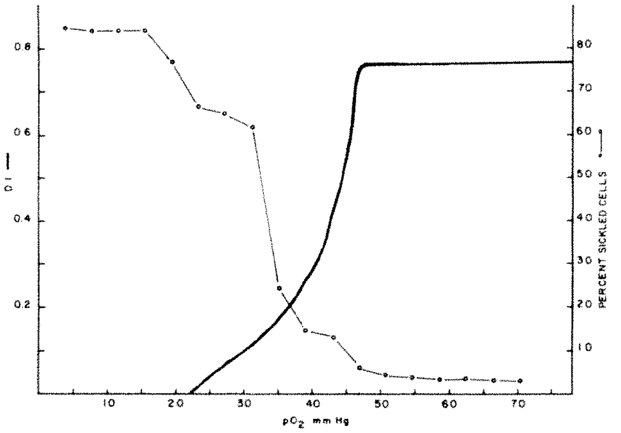
gen saturation measurements at both pH 7.2 and 7.4 to permit comparison of the results with those of Noguchi et al[7] and Noguchi[17] on polymer content, since those experiments were performed at pH 7.2. Some additional experiments were performed only at pH 7.4.

The position of the DI *v* pO_2 curve also varied with MCHC, as shown by measurements using subpopulations of sickle cells isolated on density gradients (Fig 3). Again, the shift of the curves to higher pO_2 with increasing MCHC was consistent with the known increase in polymer content with increasing MCHC for any given oxygen tension.[4,21] The DI versus pO_2 curves for unseparated cells (data not shown) were always broader than those for the gradient populations, reflecting the fact that the heterogeneous mixture of cells underwent polymerization and sickling over a broad pO_2 range.

Another variable that influenced the position of the DI *v* pO_2 curve was the viscosity of the suspending medium. A decrease in extracellular viscosity, achieved by reducing the concentration of PVP, resulted in a reduction in the proportion of deformable cells at progressively higher pO_2 values. For higher MCHC cells there was also a reduction in the maximum attainable DI (Fig 4). We attribute this latter effect to the requirement for a threshold ratio of extracellular to intracellular viscosity to induce red cell deformation.[22] A viscosity of 19.5 cp (4% PVP at 37 °C) was chosen for subsequent experiments, since this viscosity showed clear-cut deformability differences among normal red cells from different density gradient subpopulations without introducing large variations among whole blood samples from different normal subjects. It was found that if the viscosity was reduced much below 19 cp, a substantial and varying proportion of cells from normal individuals would not deform, leading to a broadening of the range of normal isotonic DI values.

Other experimental variables tested for their effect on the deformability-oxygen tension relationship included the cation composition of the suspending medium, the flow rate of the cell suspension through the gas exchange fibers, and the time period between gas exchange and deformability measurement. When cells were equilibrated in high-Na, low-K medium, the DI-pO_2 curve was shifted to higher oxygen tensions as compared to the curve obtained for cells from the same sample that were equilibrated in a medium in which the Na and K concentrations were close to their intracellular concentrations. This difference was interpreted as a reflection of a net leakage of K ions out of sickled cells in the high Na medium, resulting in a loss in cell water and a concomitant increase in HbS concentration and polymer content. Therefore the buffer that minimized transmembrane cation gradients was used for the rest of the experiments.



Relationship between the reduction in the DI signal and percentage of sickle cells for a Fraction 2 gradient population.

Table 1. Characteristics of Sickle Cell Gradient Subpopulations

Fraction	MCHC (g/dL)	Reticulocytes (%) ($\bar{X}$ ± SEM)	ISC (%)
1	26.00 ± 0.72	10.95 ± 1.14	2.12 ± 0.29
2	29.49 ± 0.44	7.84 ± 1.09	2.95 ± 0.48
3	31.21 ± 0.47	5.59 ± 0.55	3.82 ± 0.46
4	33.20 ± 0.47	4.22 ± 0.55	5.95 ± 0.60
5	34.75 ± 0.37	2.83 ± 0.80	7.58 ± 0.93
6	39.48 ± 0.91	1.40 ± 0.19	12.59 ± 1.08

The rate at which the cells were pumped through the gas exchange fibers affected the subsequent deformability of even fully oxygenated cells. If the flow rate was high (>4 mL/min), the maximum cell deformation was decreased. We surmise that this was likely the result of shear-induced fragmentation occurring as the cells entered or left the fibers. Calculation of Reynolds numbers for flow through the fibers at these rates indicates that turbulence was probably present, increasing the likelihood of cellular fragmentation. The delay time for polymer formation at low HbS concentration and at pH 7.4 was expected to be prolonged, particularly at higher levels of oxygen saturation.[23] Therefore, we wanted to determine the maximum period for which the cells could be equilibrated at 37 °C without undergoing damage and alteration in their deformability properties that could not be explained on the basis of HbS polymer formation. Variation of the equilibration period from 30 to 90 minutes had no significant effect on the DI *v* pO_2 curve (data not shown). An equilibration period of 30 minutes was chosen for the study.

We performed experiments in which 10-mL aliquots of cell suspension were run through the system while a constant pO_2 was maintained in the gas exchange system (Fig 5). Measurement of the DI at various fixed pO_2 values along the gradient range showed that the DI-pO_2 relationship obtained was very close to the continuous curve obtained using the decreasing oxygen gradient (when the continuous curve was adjusted for the spatial separation of the oxygen electrode and the ektacytometer). Therefore, we conclude that measurements performed using a decreasing gradient from 76 to 0 mm Hg oxygen provide accurate information about the proportion of sickle cells that can deform after equilibration at a given pO_2 value.

Examination of cell morphology at various points along the pO_2 gradient allowed us to define the relationship between the reduction in the DI signal and the percentage of sickle cells in a representative isolated cell population with an MCHC of 32 g/dL at pH 7.2 (Fig 6). We observed both characteristic elongated cells with spicules, and a larger

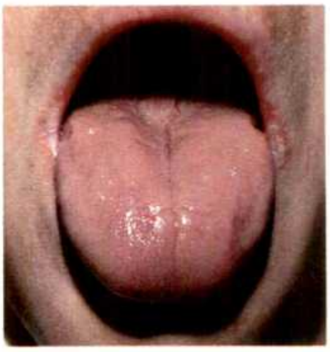
Before treatment.[1]



After treatment with MYCELEX Troche.[1]

High clinical cure* rates.

A clinical cure rate of 96% was achieved in one randomized double-blind trial[2] in which MYCELEX Troche was administered to patients with oropharyngeal candidiasis. Other investigators have concluded that MYCELEX Troche "is highly effective treatment for chronic oral candidiasis."[3]

Dramatic improvement in symptoms.

Patients attain a high degree of relief at the end of therapy, as evidenced by the dramatic decrease in severity of glossitis, patches, perleche, pain, and other clinical signs and symptoms of thrush.[4]

Good patient acceptance, minimal side effects.

With MYCELEX Troche, messy suspensions and lengthy swishing are things of the past. MYCELEX Troche has a pleasant, slightly sweet taste. And an entire day's therapy—5 troches—can easily be carried in pocket or purse.

Based on a study of 52 episodes of oropharyngeal candidiasis, the investigators stated: "We believe that the troche form of clotrimazole...in the treatment of thrush in any patient population...is both effective and safe."[2†]

*Clinical cure is defined as absence of signs and symptoms of the disease.

†See adjacent page for summary of prescribing information, including contraindications and adverse reactions.

Mycelex® Troche

(clotrimazole) 10 mg

The only troche
for oropharyngeal
candidiasis.

MYCELEX® (clotrimazole) TROCHE

Indications and Usage: Mycelex Troches are indicated for the local treatment of oropharyngeal candidiasis. The diagnosis should be confirmed by a KOH smear and/or culture prior to treatment.

Contraindications: Mycelex Troches are contraindicated in patients who are hypersensitive to any of the components.

Warning: Mycelex Troches are not indicated for the treatment of systemic mycoses.

Precautions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials. In most cases the elevations were minimal and it was often impossible to distinguish effects of clotrimazole from those of other therapy and the underlying disease (malignancy in most cases). Periodic assessment of hepatic function is advisable particularly in patients with preexisting hepatic impairment.

Since patients must be instructed to allow each troche to dissolve slowly in the mouth in order to achieve maximum effect of the medication, they must be of such an age and physical and/or mental condition to comprehend such instructions.

Carcinogenesis: An 18-month dosing study with clotrimazole in rats has not revealed any carcinogenic effect.

Usage in Pregnancy: Pregnancy Category C: Clotrimazole has been shown to be embryotoxic in rats and mice when given in doses 100 times the adult human dose (in mg/kg), possibly secondary to maternal toxicity. The drug was not teratogenic in mice, rabbits, and rats when given in doses up to 200, 180, and 100 times the human dose.

Clotrimazole given orally to mice from nine weeks before mating through weaning at a dose 120 times the human dose was associated with impairment of mating, decreased number of viable young, and decreased survival to weaning. No effects were observed at 60 times the human dose. When the drug was given to rats during a similar time period at 50 times the human dose, there was a slight decrease in the number of pups per litter and decreased pup viability.

There are no adequate and well-controlled studies in pregnant women. Clotrimazole troches should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Pediatric Use: Safety and effectiveness of clotrimazole in children below the age of three years have not been established; therefore, its use in such patients is not recommended.

Adverse Reactions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials (see Precautions section).

Nausea and vomiting was reported in about one in 20 patients.

Dosage and Administration: Mycelex Troches are administered only as a lozenge that must be dissolved slowly in the mouth. The recommended dose is one troche five times a day for 14 consecutive days. Only limited data are available on the safety and effectiveness of the clotrimazole troche after prolonged administration; therefore, therapy should be limited to short-term use, if possible.

How Supplied: Mycelex Troches—white, discoid, uncoated tablets are supplied in bottles of 70 and 140. Each tablet will be identified with the following: Miles 095.

Store below 86°F (30°C), avoid freezing.

SIX WARNING SIGNS OF KIDNEY RELATED DISEASES

Burning or difficulty during urination

More frequent urination, particularly at night

Passage of bloody-appearing urine

Puffiness around eyes, swelling of hands and feet, especially in children

Pain in small of back just below the ribs (not aggravated by movement)

High Blood Pressure

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

AN ESSENTIAL PART OF YOUR COAGULATION WORKUP

THROMBO-WELLCOTEST® THE #1 FDP TEST

A comprehensive coagulation workup isn't complete without a rapid, reliable FDP assay. That's why leading laboratories turn to THROMBO-WELLCOTEST — the #1 choice for FDP testing. THROMBO-WELLCOTEST is from Wellcome Diagnostics, so its consistent high quality is assured. And it's backed by a highly competent technical staff.

LET OUR TEAM WORK WITH YOUR TEAM

For technical information about THROMBO-WELLCOTEST, call toll free (800) 334-8570; in North Carolina call collect (919) 248-4617. To order, contact your local Wellcome Diagnostics sales representative or call toll free (800) 334-9332; in North Carolina call collect (919) 758-3436.

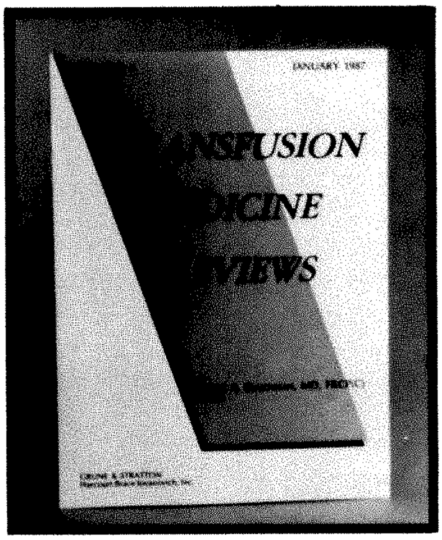
New in 1987!

TRANSFUSION MEDICINE REVIEWS

Editor-in-Chief

Morris A. Blajchman, M.D., F.R.C.P. (C)

Volume 1, 1987 (First issue, March)
Published 3 times in 1987, subsequently, quarterly, approx. 216 pages in 1987, approx. 288 pages in subsequent years
Annual subscription rate, U.S.A. and Canada: $39.00 individuals/$51.00 institutions
(All other countries: $56.00)
ISSN: 0887-7963
Journal orders must be paid in advance.
Individual journal orders must be paid by *personal* check or credit card.



This new journal provides an international forum for the publication of timely review articles on the most important clinical and research topics in transfusion medicine. The scope of the journal covers all basic science and practical aspects in the field.

Invited articles, written by acknowledged authorities, will discuss concepts of immunology, protein chemistry, genetics, molecular and cellular biology, microbiology, immunohematology, blood banking, clinical laboratory developments, and other important issues.

Interested contributors should submit an outline of their proposed articles and a tentative submission date to:

Dr. Morris A. Blajchman, Editor-in-Chief
Transfusion Medicine Reviews
Department of Pathology
McMaster University Medical Centre
1200 Main Street West
Hamilton, Ontario, Canada L8N 3Z5

Transfusion Medicine Reviews will be an authoritative journal for hematologists, technologists, nurses, and other scientific personnel involved in the provision of blood products. Medical students, residents, and fellows interested in transfusion medicine will find this a primary source of information for important issues in the field.

Scheduled topics for Vol. 1, 1987:

- Post transfusion non-A, non-B, hepatitis. *Harvey J. Alter*
- The association of blood group antigens with red cell membrane glycoproteins. *David J. Anstee.*
- The effects of red cell antigens and blood transfusion on renal transplantation. *Morris A. Blajchman*
- The role of the hematocrit in bleeding. *Bernard Boneu (with F. Fernandez)*
- Complications associated with apheresis procedures. *Marc Boogaerts*
- Controversies in the use of Rh immunoglobulin in the prevention of Rh alloimmunization. *J.M. Bowman*
- The significance of complement on the red cell surface. *John J. Freedman*
- The significance of IgG on the red cell surface. *George Garratty*
- The role of platelet glycoproteins in platelet function. *James N. George*
- Putative mechanisms of the Factor VIII bypass activity of Factor IX concentrates. *Alan Giles*
- Transfusion associated AIDS. *Jerome E. Groopman*
- The Factor VIII molecule-new perspectives. *Leon W. Hoyer*
- The use of intravenous IgG in the treatment of immune disorders. *John Kelton*
- The significance of reticuloendothelial function in the immune destruction of blood cells. *John Kelton*
- Immunogenicity of platelet membrane glycoproteins. *Tom Kunicki*
- Treatment of patients with Factor VIII antibodies. *Jeanne M. Lusher*
- Recent Developments in the Kell blood group system. *W. Laurence Marsh*
- White cell antigens and antibodies. *J. Jeffrey McCullough*
- The similarities amongst the factors affecting the successful storage of platelets and red cells. *Scott Murphy*
- ABO and Lewis antigens in tissues. *Raphael Oriol*
- The immunohematological complications of bone marrow transplantation. *Lawrence D. Petz.*
- The use of blood products for the support of bone marrow transplant recipients. *Sherrill J. Slichter*

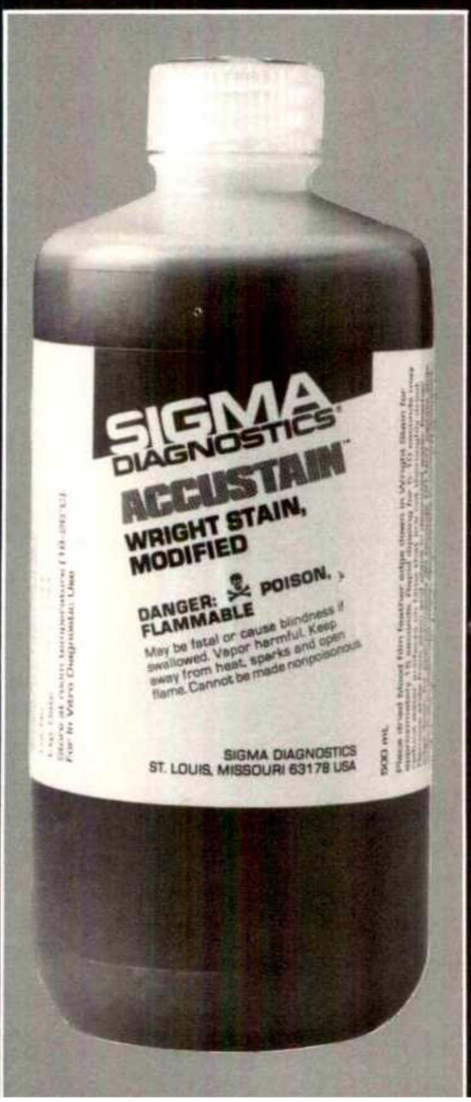
SIGMA DIAGNOSTICS NEW HEMATOLOGY TOOLS ARE BLUE, RED, PURPLE AND ALL SHADES IN-BETWEEN.

BECAUSE PEOPLE LIKE TO SEE THINGS DIFFERENTLY.

CCUSTAINS™ R HEMATOLOGY

CUSTAIN is a term now applied to a group of Sigma Diagnostics liquid ns that exhibit superior features. AC-STAINS for hematology include special nulations of Wright Stain and Giemsa in for manual and automated applica-s. For the first time, guesswork has n removed from use of Wright Stain Giemsa Stain. These materials are pared as precisely defined mixtures of hene and thiazine dyes. Their precision ufacture virtually eliminates lot-to-lot ation. The ACCUSTAINS for hema-gy exhibit consistent Romanowsky be-or, requiring no adjustment of staining es each time a new batch of material is d. This sets ACCUSTAINS apart from erials offered by other manufacturers.

stest manual reagents with perior staining characteristics.
producible results.
lot-to-lot reagent variation.
mparable manual and automated aining.
reagent precipitation problems.
usually stable reagents.
fined reagent composition.
able stain solutions for automation.
ain components manufactured by gma Diagnostics assuring maximum ality control.



SIGMA DIAGNOSTICS
ACCUSTAIN
WRIGHT STAIN, MODIFIED
DANGER: FLAMMABLE
POISON.
May be fatal or cause blindness if swallowed. Vapor harmful. Keep away from heat, sparks and open flame. Cannot be made nonpoisonous.

ADVERTISEMENT FOR HEMATOLOGIST/ONCOLOGIST

The Department of Pediatrics and Human Development at Michigan State University is seeking a Board Certified/eligible pediatric hematologist/oncologist. This individual will be a fulltime member of the department, and will work directly with the pediatric hematology/oncology group, made up of two pediatric hematologists, a nurse practitioner, a child psychologist, social worker and parent volunteers. There is a close association with the genetic and cancer research program, as well as the immunology section of the department. Facilities are available for individual research, both clinical and laboratory.

Contact: Michael L. Netzloff, M.D.,
Professor and Acting Chairman
Department of Pediatrics and
Human Development
College of Human Medicine
Michigan State University
East Lansing, Michigan 48824-1317

AFFIRMATIVE ACTION/EQUAL OPPORTUNITY INSTITUTION
Position #HM-279

Department of Pathology, University of Florida, College of Medicine is seeking a Director for the Laboratory of Cytogenetics. This is a tenure-accruing position at the Assistant Professor level with a salary commensurate with experience. Must have a Ph.D. or M.D. degree and have a strong background in cytogenetics with experience in directing a clinical cytogenetics laboratory. Position will be responsible for the interpretation of samples provided primarily by the Oncology-Hematology services. It is expected that the individual engages in original or collaborative research activities. Ample new laboratory space and facilities are available. Applicants should send curriculum vitae to Raul C. Braylan, M.D., Professor, Department of Pathology, Box J-275, University of Florida, College of Medicine, Gainesville, Florida, 32610. Application deadline of May 31, 1987 with anticipated start date of July 1, 1987.

EQUAL OPPORTUNITY/AFFIRMATIVE ACTION EMPLOYER

ASSISTANT MEMBER— CELLULAR IMMUNOLOGIST THE FRED HUTCHINSON CANCER RESEARCH CENTER

An M.D. or M.D.-PhD. with training in cellular immunology is sought to fill a position in the Transplantation Biology program at the FHCRC. Qualified candidate will be thoroughly familiar with standard means of laboratory evaluation of the immune system in human beings as a basis for the development of a collaborative research program in human bone marrow transplantation. Independent research is expected and will be encouraged, and should lead to supplemental funding for the applicant's own research activities. The candidate should also have a broad based interest in clinical immunology to take advantage of the extensive inpatient and outpatient material available for study in the Center and collaborating institutions in the city. Opportunities are available to study ontogeny and molecular biology of B and T lymphocytes, graft-versus-host disease, immunodeficiency diseases, erythropoiesis and to develop and clinically evaluate modifiers of the immune response. Laboratory space, shared facilities and start-up equipment and supply funds will be available through Center resources. Salary will be determined by Center guidelines for an assistant member. The FHCRC is an equal opportunity/affirmative action employer. Send Resume to: Transplantation Biology Program, Search Committee, Fred Hutchinson Cancer Research Center, 1124 Columbia St., M318, Seattle, WA 98104.

DIRECTION INSERT
Immune Globulin Intravenous (Human)
GAMMAGARD®

DESCRIPTION

Immune Globulin Intravenous (Human), GAMMAGARD® * is a sterile, dried, highly purified preparation of immunoglobulin which is derived from the cold ethanol fractionation process and is further purified using ultrafiltration and ion exchange adsorption. When reconstituted with the appropriate volume of diluent, this preparation contains approximately 50 mg of protein per mL, of which at least 90% is gamma globulin. The reconstituted product contains approximately 1% sodium chloride, not more than 20 mg/mL glucose, not more than 0.2 g/dL PEG, and 0.3M glycine as a stabilizing agent. It has a pH of 6.8±0.4.

The manufacturing process for Immune Globulin Intravenous (Human), GAMMAGARD, isolates gamma globulin without additional chemical or enzymatic modification and the Fc portion is maintained intact. Immune Globulin Intravenous (Human), GAMMAGARD contains all the immunoglobulin G antibody activities which are present in the donor population. On the average, the distribution of IgG subclasses present in this product is the same as is present in normal plasma.[1] Immune Globulin Intravenous (Human), GAMMAGARD contains only trace amounts of IgM and IgA.

Immune Globulin Intravenous (Human), GAMMAGARD contains no preservative.

This product has been prepared from large pools of human plasma which was taken only from plasma units found to have normal levels of alanine aminotransferase (ALT). Each unit of plasma used in the manufacture of this product has been found to be nonreactive for HBsAg and HTLV-III antibody by FDA approved tests.

CLINICAL PHARMACOLOGY

Immune Globulin Intravenous (Human), GAMMAGARD contains a broad spectrum of IgG antibodies against bacterial and viral agents that are capable of opsonization and neutralization of microbes and toxins.

Peak levels of IgG are reached immediately after infusion of Immune Globulin Intravenous (Human), GAMMAGARD. It has been shown that IgG is distributed relatively rapidly between plasma and extravascular fluid until approximately half of the total body pool is partitioned in the extravascular space. A rapid initial drop in serum levels is, therefore, to be expected.[2]

As a class, IgG survives longer *in vivo* than other serum proteins.[2,3] Studies show that the half-life of Immune Globulin Intravenous (Human), GAMMAGARD is approximately 24 days. These findings are consistent with reports of a 21 to 25 day half-life for IgG.[2,3,4] The half-life of IgG can vary considerably from person to person, however. In particular, high concentrations of IgG and hypermetabolism associated with fever and infection have been seen to coincide with a shortened half-life of IgG.[2,3,4,5]

INDICATIONS AND USAGE

Antibody Deficiency

Immune Globulin Intravenous (Human), GAMMAGARD is efficacious in the treatment of primary immunodeficient states in which severe impairment of antibody forming capacity has been shown, such as: congenital agammaglobulinemias, common variable immunodeficiency, Wiskott-Aldrich syndrome, and severe combined immunodeficiencies.[4,5]

Immune Globulin Intravenous (Human), GAMMAGARD is especially useful when high levels or rapid elevation of circulating gamma globulins are desired or when intramuscular injections are contraindicated.

CONTRAINDICATIONS

None known.

WARNINGS

Immune Globulin Intravenous (Human), GAMMAGARD should only be administered intravenously. Other routes of administration have not been evaluated.

Immune Globulin Intravenous (Human), GAMMAGARD contains very low quantities of IgA (not more than 10 μg/mL) and although no instances of anaphylaxis associated with the use of this product have been observed during the clinical trials, such reactions have been observed with other immunoglobulin products.[5,6] Immune Globulin Intravenous (Human), GAMMAGARD should be given with caution to patients with antibodies to IgA or selective IgA deficiencies.

PRECAUTIONS

Drug Interaction

Admixtures of Immune Globulin Intravenous (Human), GAMMAGARD with other drugs have not been evaluated. It is recommended that Immune Globulin Intravenous (Human), GAMMAGARD be administered separately from other drugs or medication which the patient may be receiving.

Pregnancy Category C

Animal reproduction studies have not been conducted with Immune Globulin Intravenous (Human), GAMMAGARD. It is also not known whether Immune Globulin Intravenous (Human), GAMMAGARD can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Immune Globulin Intravenous (Human), GAMMAGARD should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

The incidence of untoward reactions to Immune Globulin Intravenous (Human), GAMMAGARD is low, although various minor reactions, such as headache, fatigue, chills, backache, lightheadedness, fever and nausea may occasionally occur. The incidence of these reactions during the clinical trials was less than 6%. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Immediate anaphylactic and hypersensitivity reactions due to previous sensitization, although they have not been observed during the clinical trials, are a possibility. Epinephrine should be available for treatment of any acute anaphylactoid reaction. (See WARNINGS.)

DOSAGE AND ADMINISTRATION

Antibody Deficiency

For patients with primary immunodeficiencies, monthly doses of at least 100 mg/kg are recommended. Initially, patients may receive 200-400 mg/kg. As there are significant differences in the half-life of IgG among patients with primary immunodeficiencies, the frequency and amount of immunoglobulin therapy may vary from patient to patient. The proper amount can be determined by monitoring clinical response and/or the serum IgG levels before each dose, to insure that they do not drop below 500 mg/dL.

Rate of Administration

It is recommended that initially a rate of 0.5 mL/kg per Hr be used. If infusion at this rate causes the patient no distress, the administration rate may be gradually increased but should not exceed 4 mL/kg per Hr.

A rate of administration which is too rapid may cause flushing and changes in pulse rate and blood pressure. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Administration

Immune Globulin Intravenous (Human), GAMMAGARD should be administered as soon after reconstitution as possible. Administration should not begin more than 2 hours after reconstitution.

The reconstituted material should be at room temperature during administration.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Follow directions for use which accompany the administration set. If a Hyland set is not used, make sure the administration set contains an adequate filter.

How Supplied

Immune Globulin Intravenous (Human), GAMMAGARD is supplied in either 2.5 g or 5.0 g single use vials. Each vial of Immune Globulin Intravenous (Human), GAMMAGARD is furnished with a suitable volume of Sterile Water for Injection, USP, a transfer device and an administration set which contains an integral airway and a 15 micron filter.

Storage

Immune Globulin Intravenous (Human), GAMMAGARD should be stored under ordinary refrigeration, (2 to 8 °C, 36 to 46 °F). Freezing should be avoided to prevent the diluent bottle from breaking.

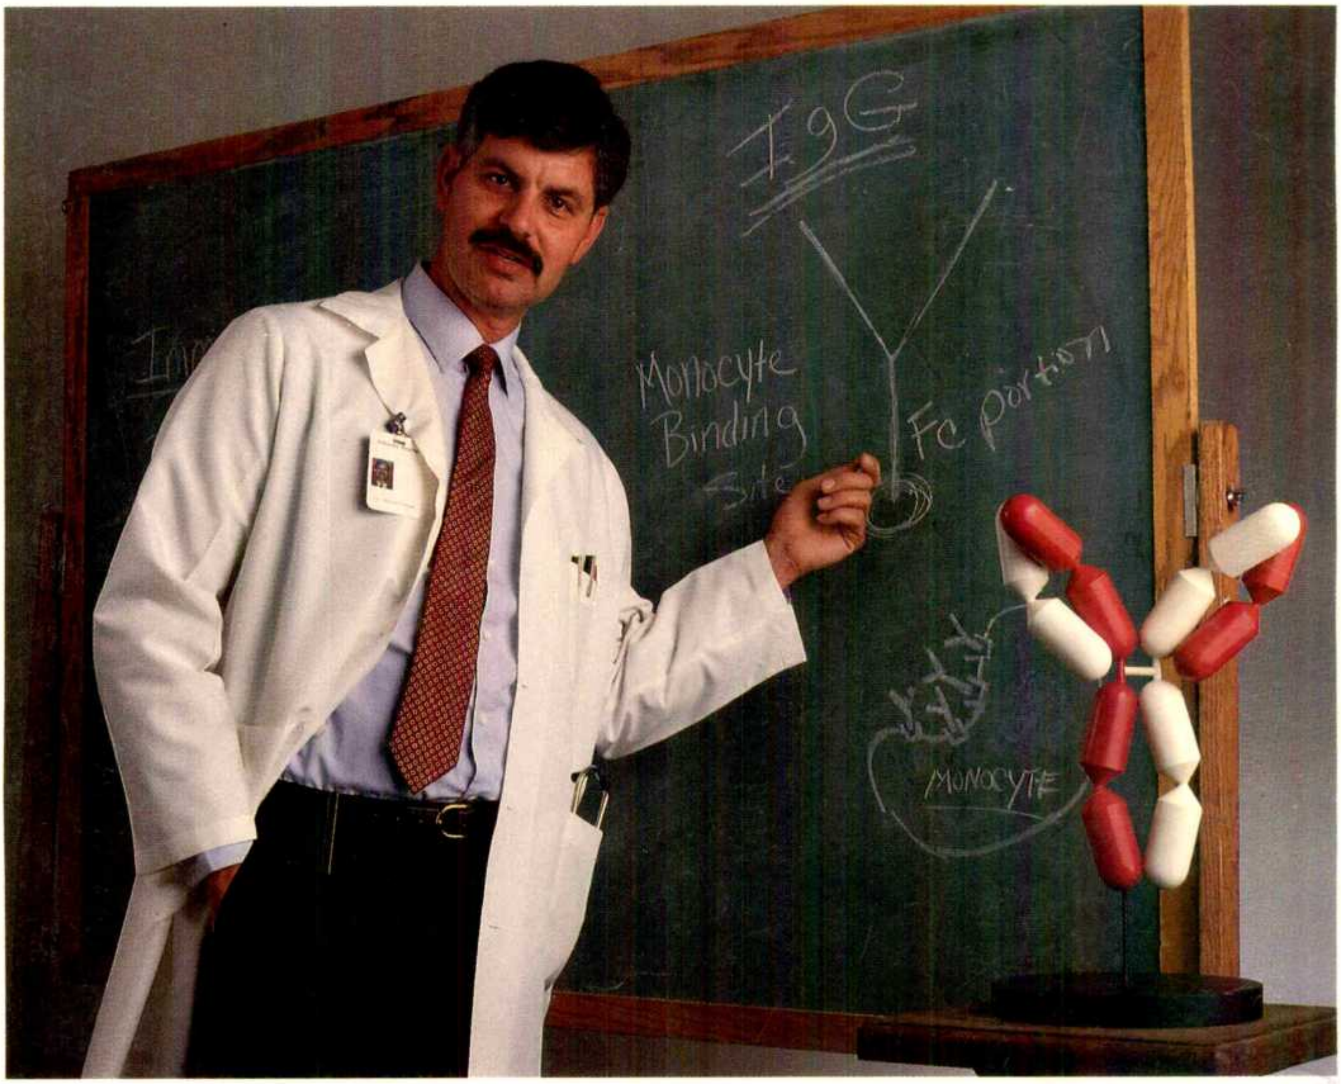
The efficacy of an IGIV depends on the process used to make it.



GAMMAGARD®
Immune Globulin Intravenous (Human)

Efficacy from an Immune Globulin Intravenous (IGIV) depends on many closely-linked factors. To function best, the entire IgG molecule should be undamaged – that is, intact. This lets the Fab portion bind antigens and the Fc section – the base of the "Y" – interact with a monocyte's Fc receptors. These capabilities are, in large part, what enables IgG to mediate phagocytosis.

A recent study compared the ability of various IGIVs to bind with human monocyte Fc receptors. Those isolated by DEAE-Sephadex purification conserved the capacity of IgG to interact with Fc receptors[1]. One product preserved more of this capacity than all other preparations tested: GAMMAGARD® IGIV, which is produced by Travenol's patented DEAE-Sephadex adsorption method. When your immunocompromised patients need an IGIV, specify GAMMAGARD® IGIV.

Thousands of P

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

Burroughs Wellcome Co.
3030 Cornwallis Road

atients Rescued

WELLCOVORIN® TABLETS

(leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.[1]

[1] Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

Please see brief summary of prescribing information on next pa

WELLCOVORIN® TABLETS
(leucovorin calcium)
Leucovorin in convenient 5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

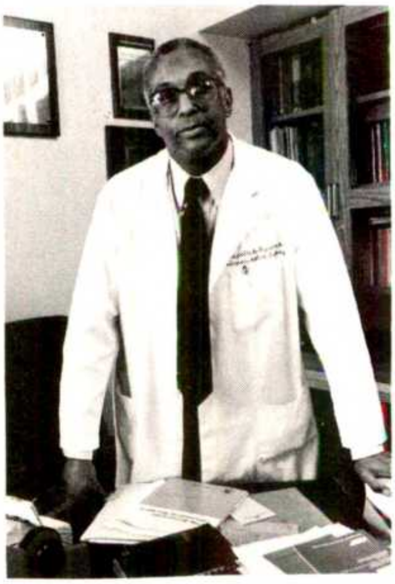
THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

You can help us raise the colorectal cancer cure rate.



"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces cancer alone.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

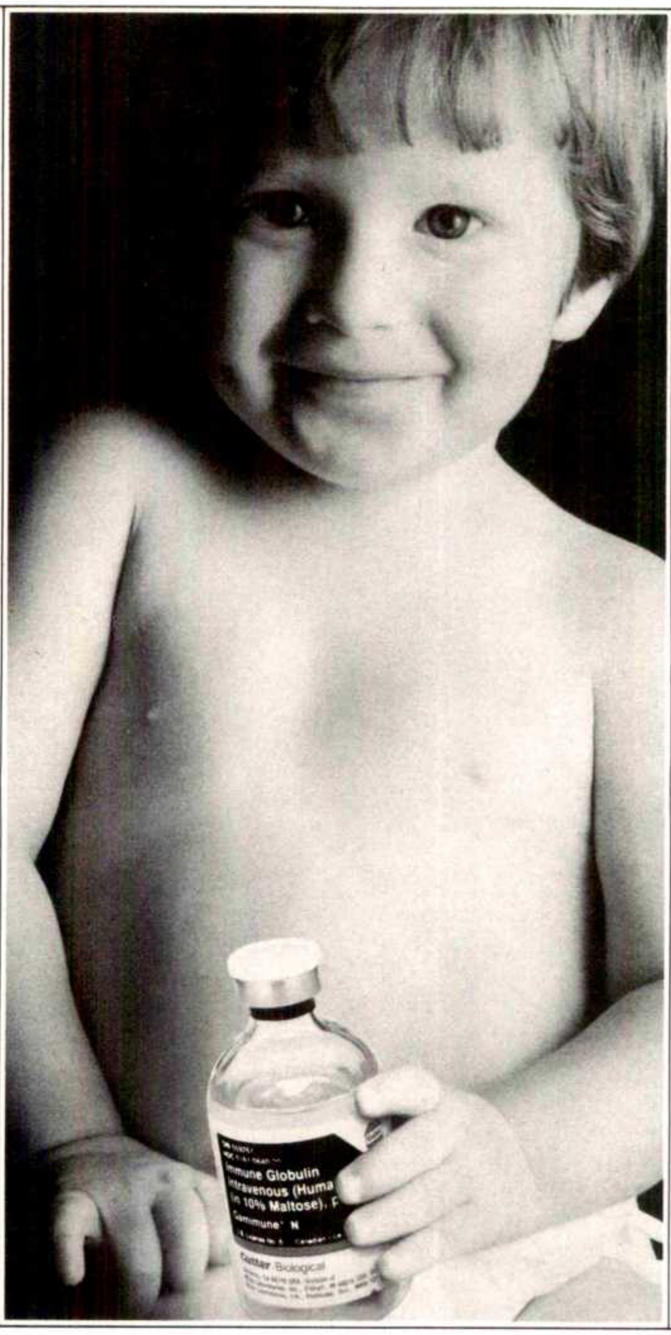
Today's IGIV. Don't settle for less.

For immunodeficiency syndromes: aggressive protection against infection

Patients without sufficient levels of antibodies face overwhelming infection, and they need help. Infusion with GAMIMUNE® N gives these patients the edge that may make the difference: antibodies against major bacterial, viral and fungal pathogens... in just minutes.

For both chronic and acute ITP in children and adults: rapid elevation of platelet levels

GAMIMUNE® N may initiate a therapeutic increase in platelets in both children and adults with idiopathic thrombocytopenic purpura (ITP).[1*†] Treatment with GAMIMUNE® N has enabled some ITP patients to undergo major surgery.[1]

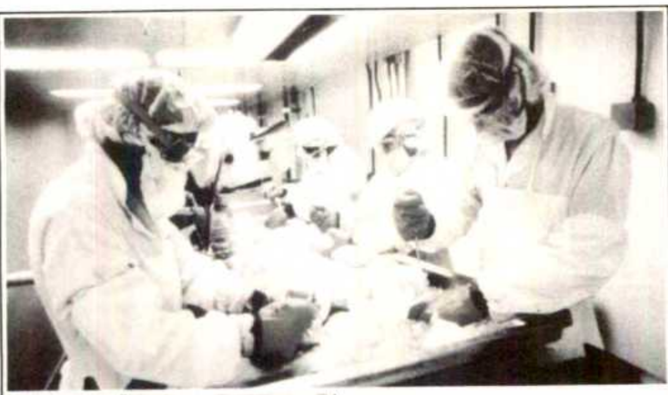


IGIV that's at least 98% pure gamma globulin

Cutter's fractionation method (Cohn-Oncley 6 & 9) contains all the necessary steps to produce high purity immune globulin. GAMIMUNE® N contains no foreign contaminants, no detectable levels of protein aggregates or vasoactive enzymes.[2] With GAMIMUNE® N you get what you expect ...IGIV containing at least 98% pure gamma globulin.[1]

GAMIMUNE® N

Immune Globulin
Intravenous (Human) 5%
(in 10% Maltose), pH 4.25

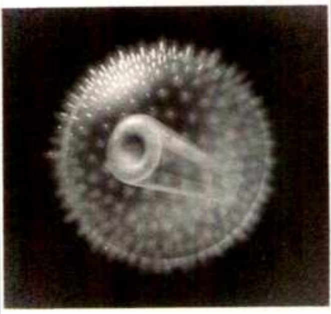


"Native" IGIV

GAMIMUNE® N is manufactured without chemical modification. This means GAMIMUNE® N antibodies maintain normal opsonization capacity, have a normal distribution of IgG subgroups and provide the immunologic activity of normal plasma.[1]

Documented in vitro inactivation of HTLV-III virus[‡]

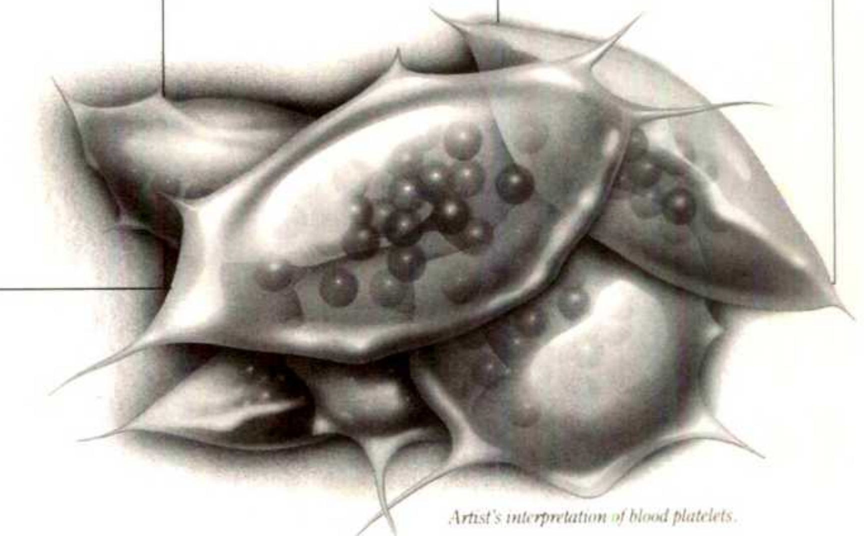
[‡] The Cohn-Oncley process used to produce Gamimune®N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HTLV-III and found to remove and/or inactivate the viral challenge. In addition, Gamimune®N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 TCID (Tissue Culture Infectious Doses) reduction of HTLV-III.[3]



Artist's interpretation of HTLV-III virus.

Today's simple, economical IGIV: the only ready-to-use liquid

Dose for dose, GAMIMUNE® N saves money by eliminating valuable reconstitution time in the pharmacy. Gram for gram of protein, GAMIMUNE® N is affordable; there is no premium price for TODAY'S IGIV.



Artist's interpretation of blood platelets.

From the original IGIV, today's IGIV...it offers more

Please see following page for brief summary of prescribing information.

---

[*] It is not possible to predict which patients with ITP will respond to therapy.

[†] In patients who respond to therapy, a rise in platelet count is generally rapid (within 1 to 5 days), transient (most often lasting from several days to several weeks) and should not be considered curative.

GAMIMUNE® N
Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune* N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune* N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune* N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune* N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune* N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune* N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune* N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune* N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune* N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune* N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune* N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune* N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune* N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune* N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune* N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune* N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune* N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune* N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune* N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1–5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune* N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune* N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune* N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune* N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune* N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune* N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune* N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune* N. It is not known whether Gamimune* N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune* N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune* N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune* N. Symptoms reported with Gamimune* N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune* N at the infusion site was reported in some cases.

In further studies of Gamimune* N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune* N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune* N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune* N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune* N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune* N for prophylaxis in immunodeficiency syndromes is 100–200 mg/kg (2–4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune* N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune* N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune* N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune* N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Read this like your life depends on it.

Breast cancer found early and treated promptly has an excellent chance for cure. About a week after your period, when breasts are normal, practise this self-exam. Ask your doctor to teach you this method:

1. In bath or shower. Fingers flat, move opposite hand gently over each breast. Check for lumps, hard knots, thickening.

2. In front of a mirror. Observe breasts. Arms at sides. Raise arms high overhead. Any change in nipples, contours, swelling, dimpling of skin? Palms on hips: press down firmly to flex chest muscles. Breasts do not usually match.

3. Lying down. Pillow under right shoulder, right hand behind head. Left hand fingers flat, press gently in small circular motions starting at 12 o'clock. Make about three circles moving closer to and including nipple. Reverse and repeat on left.

RETROVIR® (zidovudine)

The first effective treatment for certain AIDS and other serious HIV* infections

AZT™ (azidothymidine)
IS NOW
RETROVIR® (zidovudine)

---

*Human immunodeficiency virus

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR® (zidovudine)

New hope for many AIDS/ARC patients

A multicenter study proved…

RETROVIR can prolong the lives of certain AIDS and ARC patients

- In a double-blind placebo-controlled clinical trial (N = 281), only one death occurred among 144 RETROVIR patients *v* 19 deaths of the 137 patients on placebo ($p<0.001$). The study population consisted of AIDS patients within 120 days of their first diagnosis of *Pneumocystis carinii* pneumonia or patients with more severe manifestations of AIDS-related complex (ARC)
- The probability of 24-week survival for any patient in the RETROVIR group was 0.98 compared to 0.78 for the placebo group

Comparative Mortality of RETROVIR and Placebo Group Patients in Controlled Clinical Trial (stratified by diagnosis and T4 count) n = 281

Stratum	Group Assigned	Number of Deaths
AIDS (n=160)	RETROVIR	1
	PLACEBO	12
ARC (n=121)	RETROVIR	0
	PLACEBO	7

Stratum	Group Assigned	Number of Deaths
Higher T4 count ($\geq$100 $\leq$500) (n=100)	RETROVIR	0
	PLACEBO	4
Lower T4 count (<100) (n=181)	RETROVIR	1
	PLACEBO	15

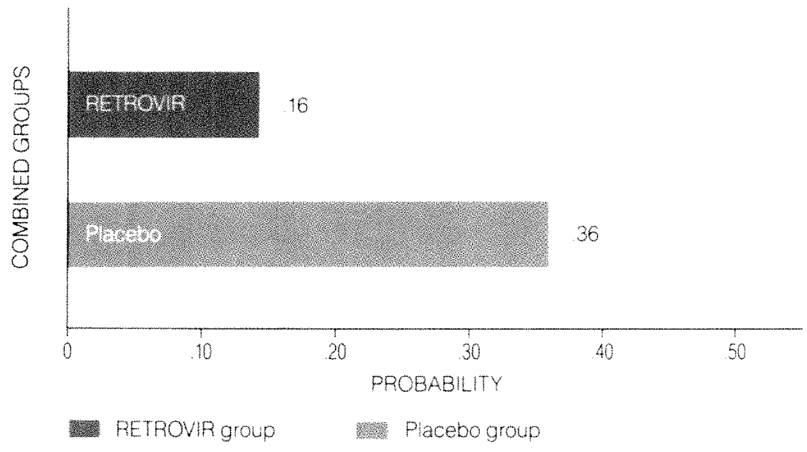
Total Deaths	RETROVIR	1
	PLACEBO	19

RETROVIR® (zidovudine) reduced the risk and severity of opportunistic infections

- RETROVIR significantly reduced the probability of acquiring opportunistic infections in AIDS and ARC patients ($p<0.001$)
- Severity of opportunistic infections was significantly reduced in RETROVIR patients as compared with controls ($p<0.005$)
- In the controlled trial, no opportunistic infections occurred in ARC patients who had received at least six weeks of RETROVIR therapy. Some ARC patients developed opportunistic infections in the follow-up period while on drug

Probability of Developing Opportunistic Infection Within 24 Weeks

(Excludes opportunistic infections acquired within six weeks of entry into the study)



Please see brief summary of prescribing information on last page of this advertisement.

WARNING

WARNING: Therapy with RETROVIR® (zidovudine) is often associated with hematologic toxicity including granulocytopenia and severe anemia requiring transfusions (see WARNINGS). In addition, patients treated with zidovudine may continue to develop opportunistic infections (OI's) and other complications of the acquired immunodeficiency syndrome (AIDS) and AIDS-related complex (ARC) caused by the human immunodeficiency virus (HIV). Therefore, patients on zidovudine should be under close clinical observation by physicians experienced in the treatment of patients with diseases associated with HIV. The safety and efficacy of zidovudine have been established only for certain adult AIDS and advanced ARC patients (see INDICATIONS AND USAGE).

IMPROVING LIVES THROUGH
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

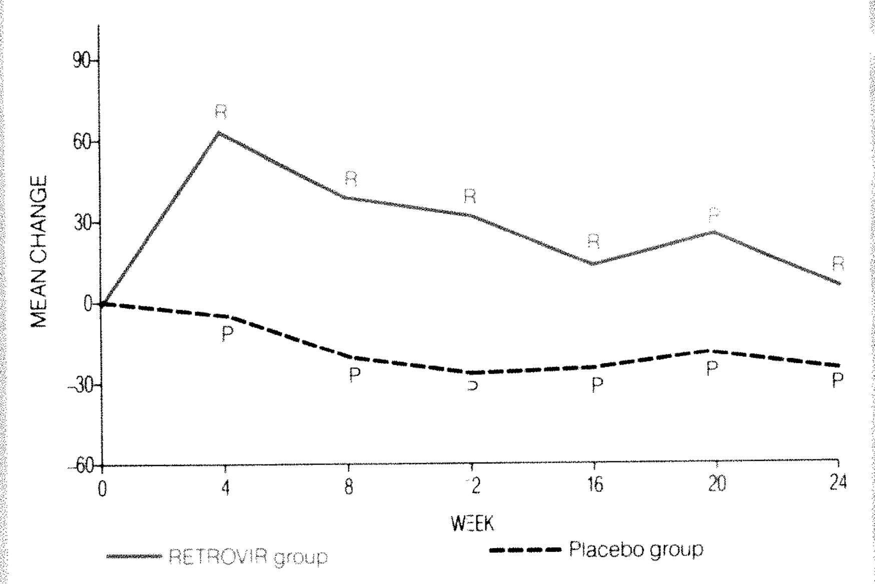
RETROVIR® (zidovudine)

New hope for many AIDS/ARC patients

RETROVIR improved immune status

- T4 cell counts in the RETROVIR group remained significantly higher than in the control group throughout the study
  - In some RETROVIR patients, particularly those with lower T4 cell counts at entry, T4 cell numbers increased, then subsequently declined
  - In contrast, placebo-group patients experienced a progressive decline from baseline in number of T4 cells
- The number of positive delayed hypersensitivity skin test conversions was significantly higher in the RETROVIR group ($p<0.001$)

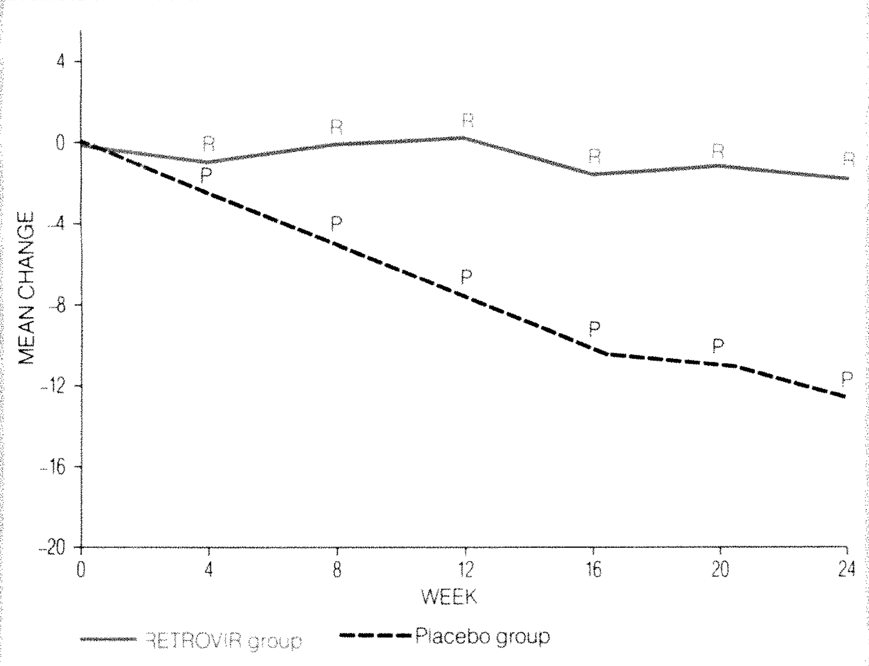
Change in T4 Cell Count



Patients' general health improved

- Patients on RETROVIR® (zidovudine) maintained their high Karnofsky performance scores (an index measuring ability to perform activities of daily life), whereas placebo group patients' scores declined
- RETROVIR patients experienced significantly fewer symptoms related to HIV infection than those on placebo
- Patients on RETROVIR therapy maintained their body weight throughout the study, whereas placebo group patients progressively lost weight

Change in Karnofsky Score for All AIDS/ARC Patients Combined



Please see brief summary of prescribing information on last page of this advertisement.

IMPROVING LIVES THROUGH
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

RETROVIR® (zidovudine)

New hope
for many AIDS/ARC patients

Clinical studies showed...

It is important to identify patients at greatest risk for bone marrow toxicity, and subsequent RBC and WBC suppression, and monitor carefully

- 25% of RETROVIR patients developed anemia (<7.5 g/dl) as compared to 4% in the placebo group. This adverse reaction was most likely to occur in AIDS patients and patients with lower numbers of T4 cells
- 31% of RETROVIR patients required at least one transfusion, compared with 11% of placebo patients
- Granulocyte depression (<750/mm^3) was observed in 39% of RETROVIR patients as compared with 9% of placebo patients. Granulocytopenia occurred more frequently in AIDS patients and patients with lower T4 cell counts

Clinical adverse events

- Although the majority of patients in *both* the RETROVIR (84%) and control groups (72%) reported the occurrence of at least one adverse event, nausea, myalgia, insomnia, and moderate-to-severe headache were significantly more frequent among RETROVIR patients

The potential hematologic toxicity of RETROVIR plays an important role in patient management

- The majority of patients who required adjustment of RETROVIR dosage had hematologic toxicity, specifically anemia or granulocytopenia, usually occurring within the first four to eight weeks of RETROVIR therapy
- Because of this potential, careful monitoring of hematologic indices is recommended every two weeks*

Drug interactions must be considered with RETROVIR

- Concomitant use of acetaminophen with RETROVIR may potentiate granulocytopenia; other drugs that may interfere with RETROVIR metabolism or excretion (eg, probenecid, lorazepam, indomethacin, cimetidine) should be avoided

RETROVIR—the newest antiviral breakthrough from Burroughs Wellcome Co.—is the first effective treatment for certain HIV infections.

---

*RETROVIR dose interruption may be required for significant anemia or granulocytopenia until evidence of bone marrow recovery is observed. A reduction in daily dose may be adequate for less severe depression of RBC/WBC counts.

Since the initial supply of RETROVIR® (zidovudine) is limited, a special distribution program is in place

- Rapidity of development and complexity of the production process have limited the current supply of RETROVIR
- To help ensure a continuous supply of RETROVIR for patients at greatest need and those who would benefit most from treatment during this period of limited supply, a special distribution program has been established
- An independent group of experts from the Infectious Disease Society of America (IDSA) has assisted in developing this program for the best utilization of RETROVIR

Patients can be enrolled in the RETROVIR distribution program now

- You can apply to enroll your patients in the RETROVIR distribution program at this time
- If you are currently treating AIDS or ARC patients and need additional information, call 1-800-843-9388
- Detailed information and enrollment applications are also available from your Burroughs Wellcome Co. Sales Representative
- Only patients enrolled in the distribution program will be able to receive RETROVIR

Burroughs Wellcome Co.: Leader in Antiviral Research

- Continuing clinical trials to evaluate further the role of RETROVIR in the treatment of HIV infections
- Conducting research for antiviral agents effective against varicella-zoster, Epstein-Barr, human papilloma, hepatitis B virus, and cytomegalovirus
- Providing physicians with antiviral products effective against herpes simplex — today's hope for patients with genital herpes
- **Pledging to keep you updated as new information becomes available**

If you have patients with HIV infections and need additional information, please call

RETROVIR® (ZIDOVUDINE) Capsules

WARNING: THERAPY WITH RETROVIR (ZIDOVUDINE) IS OFTEN ASSOCIATED WITH HEMATOLOGIC TOXICITY INCLUDING GRANULOCYTOPENIA AND SEVERE ANEMIA REQUIRING TRANSFUSIONS (SEE WARNINGS).

IN ADDITION, PATIENTS TREATED WITH ZIDOVUDINE MAY CONTINUE TO DEVELOP OPPORTUNISTIC INFECTIONS (OI'S) AND OTHER COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) AND AIDS RELATED COMPLEX (ARC) CAUSED BY THE HUMAN IMMUNODEFICIENCY VIRUS (HIV). THEREFORE, PATIENTS ON ZIDOVUDINE SHOULD BE UNDER CLOSE CLINICAL OBSERVATION BY PHYSICIANS EXPERIENCED IN THE TREATMENT OF PATIENTS WITH DISEASES ASSOCIATED WITH HIV. THE SAFETY AND EFFICACY OF ZIDOVUDINE HAVE BEEN ESTABLISHED ONLY FOR CERTAIN ADULT AIDS AND ADVANCED ARC PATIENTS (SEE "INDICATIONS AND USAGE").

INDICATIONS AND USAGE: Retrovir Capsules are indicated for the management of certain adult patients with symptomatic HIV infection (AIDS and advanced ARC) who have a history of cytologically confirmed *Pneumocystis carinii* pneumonia (PCP) or an absolute CD4 (T4 helper/inducer) lymphocyte count of less than $200/mm^3$ in the peripheral blood before therapy is begun.

This indication is based primarily on the results of a randomized, double-blind, placebo-controlled trial conducted at 12 medical centers in the United States in which 281 patients with AIDS or advanced ARC were studied for an average of four and a half months. Additional data have been collected on approximately 80% of these patients who have received zidovudine in an open-label extension of this trial for an average of five more months.

The patient population of the controlled trial consisted of 160 AIDS patients (85 Retrovir and 75 placebo) who had recovered from their first episode of PCP diagnosed within the previous four months, and 121 ARC patients (59 Retrovir and 62 placebo) with multiple signs and symptoms of HIV infection, including mucocutaneous candidiasis and/or unexplained weight loss ($\geq$ 15 lbs or $>$ 10% of prior body weight). All patients had evidence of impaired cellular immunity with an absence of delayed cutaneous hypersensitivity and a decreased number of CD4 (T4) lymphocytes in the peripheral circulation. Two hundred twenty-one (79% of all patients) had fewer than 200 T4 $cells/mm^3$ at entry (95% of AIDS patients and 57% of ARC patients). All patients began therapy at a dose of 250 mg every 4 hours around the clock. This dosage was reduced or temporarily or permanently discontinued if serious marrow toxicity occurred. The trial was stopped because of a significant reduction in mortality before all patients had completed the planned 24 weeks of treatment. There were 19 deaths in the placebo group and 1 in the Retrovir group ($p < .001$). All deaths were apparently due to opportunistic infections (OI) or other complications of HIV infection. Treatment duration ranged from 12 weeks to 26 weeks, with a mean and median duration of 17 and 18 weeks, respectively.

Retrovir also significantly reduced the risk of acquiring an AIDS-defining OI in patients after 6 weeks of treatment ($p < .001$). In addition, patients who received Retrovir generally did better than the placebo group in terms of several other measures of efficacy including performance level, neuropsychiatric function, maintenance of body weight and the number and severity of symptoms associated with HIV infection. A modest increase in mean CD4 (T4) counts was seen in the zidovudine group but the significance of this finding is unclear as the CD4 (T4) counts declined again in some patients.

The most significant adverse reaction noted in the study was a depression of formed elements in the peripheral blood, which necessitated dose reduction or drug discontinuation in 49 of the 144 (34%) patients receiving Retrovir. Of those participants whose baseline CD4 (T4) lymphocyte counts were less than 200, 47% of those receiving Retrovir and 10% of those receiving placebo developed a granulocyte count of $<750/mm^3$. Similarly, 45% of Retrovir recipients and only 14% of placebo recipients had a 25% or greater reduction in hemoglobin. (See ADVERSE REACTIONS.)

At the conclusion of the placebo-controlled trial, 127 Retrovir recipients and 100 placebo recipients elected to enroll in an uncontrolled extension protocol in which all patients received Retrovir at a dose of 200 mg every four hours. This dose was chosen because of concern about cumulative hematologic toxicity and to allow for greater flexibility in dosing. Over the subsequent five months, opportunistic infections continued to occur and additional patients died in both groups. Sixteen patients from the original placebo cohort died after the conclusion of the controlled trial. Four of these 16 never received Retrovir and seven expired during the first month of therapy. Ten additional deaths occurred among the original Retrovir recipients. With respect to these data, termination of the controlled trial precludes direct comparisons of mortality and morbidity between the original placebo and drug recipients. Long-term follow-up of these patients, however, will allow for examination of the natural history of prolonged zidovudine therapy.

CONTRAINDICATIONS: Retrovir Capsules are contraindicated for patients who have potentially life-threatening allergic reactions to any of the components of the formulation.

WARNINGS: Zidovudine has been carefully studied in limited numbers of seriously ill HIV-infected patients treated for a limited period of time. Therefore, the full safety and efficacy profile of zidovudine has not been completely defined, particularly in regard to prolonged use, and especially in HIV-infected individuals who have less advanced disease.

Zidovudine should be used with extreme caution in patients who have bone marrow compromise evidenced by granulocyte count $<$ $1000/mm^3$ or hemoglobin $<$ 9.5 g/dl. In the placebo-controlled study, anemia and granulocytopenia were the most significant adverse events observed (see ADVERSE REACTIONS).

Significant anemia most commonly occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions. Frequent (at least every 2 weeks) blood counts are strongly recommended in patients taking zidovudine. If anemia or granulocytopenia develops, dosage adjustments may be necessary (see DOSAGE AND ADMINISTRATION).

Coadministration of zidovudine with other drugs metabolized by glucuronidation should be avoided because the toxicity of either drug may be potentiated (see Drug Interactions under PRECAUTIONS). Zidovudine recipients who used acetaminophen during the controlled trial had an increased incidence of granulocytopenia which appeared to be correlated with the duration of acetaminophen use.

PRECAUTIONS:

General: Zidovudine is eliminated from the body primarily by renal excretion following metabolism in the liver (glucuronidation). There are currently no data available concerning the use of zidovudine in patients with impaired renal or hepatic function, and such patients may be at a greater risk of toxicity from zidovudine.

Drug Interactions: The interaction of other drugs with zidovudine has not been studied in a systematic manner. Coadministration of zidovudine with drugs that are nephrotoxic, cytotoxic, or which interfere with RBC/WBC number or function (e.g., dapsone, pentamidine, amphotericin B, flucytosine, vincristine, vinblastine, adriamycin, or interferon) may increase the risk of toxicity. Limited data suggest that probenecid may inhibit glucuronidation and/or reduce renal excretion of zidovudine. In addition, other drugs (e.g., acetaminophen, aspirin, or indomethacin) may competitively inhibit glucuronidation (see WARNINGS).

Some experimental nucleoside analogues which are being evaluated in AIDS and ARC patients may affect RBC/WBC number or function and may increase the potential for hematologic toxicity of zidovudine. Some experimental nucleoside analogues affecting DNA replication antagonize the *in vitro* antiviral activity of zidovudine against HIV and thus, concomitant use of such drugs should be avoided.

Some drugs such as trimethoprim-sulfamethoxazole, pyrimethamine, and acyclovir may be necessary for the management or prevention of opportunistic infections. In the controlled trial, increased toxicity was not detected with limited exposure to these drugs. However, there are two published reports of neurotoxicity (one of profound lethargy and one of seizure) associated with concomitant use of zidovudine and acyclovir.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies of zidovudine in animals have not been completed. However, in an *in vitro* mammalian cell transformation assay, zidovudine was positive at concentrations of 0.5 μg/ml and higher.

No evidence of mutagenicity (with or without metabolic activation) was observed in the Ames *Salmonella* mutagenicity assay. In a mutagenicity assay conducted in L5178Y/$TK^{+/-}$ mouse lymphoma cells, zidovudine was weakly mutagenic in the absence of metabolic activation only at the highest concentrations tested (4000 and 5000 μg/ml). In the presence of metabolic activation, the drug was weakly mutagenic at concentrations of 1000 μg/ml and higher. In an *in vitro* cytogenetic study performed in cultured human lymphocytes, zidovudine induced dose-related structural chromosomal abnormalities at concentrations of 3 μg/ml and higher. No such effects were noted at the two lowest concentrations tested, 0.3 and 1 μg/ml.

Pregnancy: Pregnancy Category C. An oral teratology study in pregnant rats using doses up to 20 times the human dose has revealed no evidence of harm to the fetus due to zidovudine. It is not known whether zidovudine can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Zidovudine should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether zidovudine is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions from zidovudine in nursing infants, mothers should be instructed to discontinue nursing if they are receiving zidovudine.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequent adverse events and abnormal laboratory values reported in the placebo-controlled clinical trial of oral zidovudine administration in 281 patients (144 patients zidovudine; 137 patients placebo) were granulocytopenia and anemia. The occurrence of these hematologic toxicities was inversely related to CD4 (T4) lymphocyte number, hemoglobin, and granulocyte count at study entry, and directly releated to dose and duration of therapy. The frequency of granulocytopenia and anemia according to the patients' CD4 (T4) levels is shown in the following table:

	Pretreatment CD4 (T4) Levels			
	$\leq 200/mm^3$		$>200/mm^3$	
Abnormality	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia ($< 750/mm^3$)	47%	10%	10%	3%
Anemia (Hgb <7.5 g/dl)	30%	6%	3%	0%

Because many patients were anemic and/or granulocytopenic before starting therapy with zidovudine, examining the degree of change when compared to baseline, as shown in the table below, may be more informative.

		Pretreatment CD4 (T4) Levels			
		$\leq 200/mm^3$		$>200/mm^3$	
Abnormality	% Decrease from Baseline	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia	>50%	55%	19%	40%	13%
Anemia	>25%	45%	14%	10%	10%

The anemia appeared to be the result of impaired erythrocyte maturation as evidenced by increasing macrocytosis (MCV) while on drug.

The 281 patients treated in this controlled trial had serious underlying disease with multiple baseline symptoms and clinical abnormalities. The following table summarizes those reported clinical adverse events which occurred in at least 5% of all patients treated with zidovudine. Severe headache, nausea, insomnia and myalgia were reported at a significantly greater rate in zidovudine recipients.

Percentage (%) of Patients with Clinical Events					
Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %	Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %
BODY AS A WHOLE			MUSCULOSKELETAL		
Asthenia	19	18	Myalgia	8	2
Diaphoresis	5	4	NERVOUS		
Fever	16	12	Dizziness	6	4
Headache	42	37	Insomnia	5	1
Malaise	8	7	Paresthesia	6	3
GASTROINTESTINAL			Somnolence	8	9
Anorexia	11	8	RESPIRATORY		
Diarrhea	12	18	Dyspnea	5	3
Dyspepsia	5	4	SKIN		
GI Pain	20	19	Rash	17	15
Nausea	46	18	SPECIAL SENSES		
Vomiting	6	3	Taste Perversion	5	8

Clinical adverse events which occurred in less than 5% of all patients treated with zidovudine are listed below. Since many of these adverse events were seen in placebo-treated patients as well as zidovudine recipients, they may not be attributable to the drug.

Body as a whole: body odor, chills, edema of the lip, flu syndrome, hyperalgesia, back pain, chest pain, lymphadenopathy.
Cardiovascular: vasodilation.
Gastrointestinal: constipation, dysphagia, edema of the tongue, eructation, flatulence, bleeding gums, rectal hemorrhage, mouth ulcer.
Musculoskeletal: arthralgia, muscle spasm, tremor, twitch.
Nervous: anxiety, confusion, depression, emotional liability, nervousness, syncope, loss of mental acuity, vertigo.
Respiratory: cough, epistaxis, pharyngitis, rhinitis, sinusitis, hoarseness.
Skin: acne, pruritus, urticaria.
Special senses: amblyopia, hearing loss, photophobia.
Urogenital: dysuria, polyuria, urinary frequency, urinary hesitancy.

DOSAGE AND ADMINISTRATION: The recommended starting dose of Retrovir (zidovudine) is 200 mg (two 100 mg capsules) administered orally every four hours around the clock.

Hematologic toxicities appear to be related to pretreatment bone marrow reserve and to dose and duration of therapy. Careful monitoring of hematologic indices every two weeks is recommended to detect serious anemia or granulocytopenia. In patients with hematologic toxicity, reduction in hemoglobin may occur as early as 2 to 4 weeks, and granulocytopenia usually occurs after 6 to 8 weeks.

Dose Adjustment: Significant anemia (hemoglobin of <7.5 g/dL or reduction of >25% of baseline) and/or significant granulocytopenia (granulocyte count of $<750/mm^3$ or reduction of >50% from baseline) may require a dose interruption until some evidence of marrow recovery is observed. For less severe anemia or granulocytopenia, a reduction in daily dose may be adequate. In patients who develop significant anemia, dose modification does not necessarily eliminate the need for transfusion. If marrow recovery occurs following dose modification, gradual increases in dose may be appropriate depending on hematologic indices and patient tolerance.

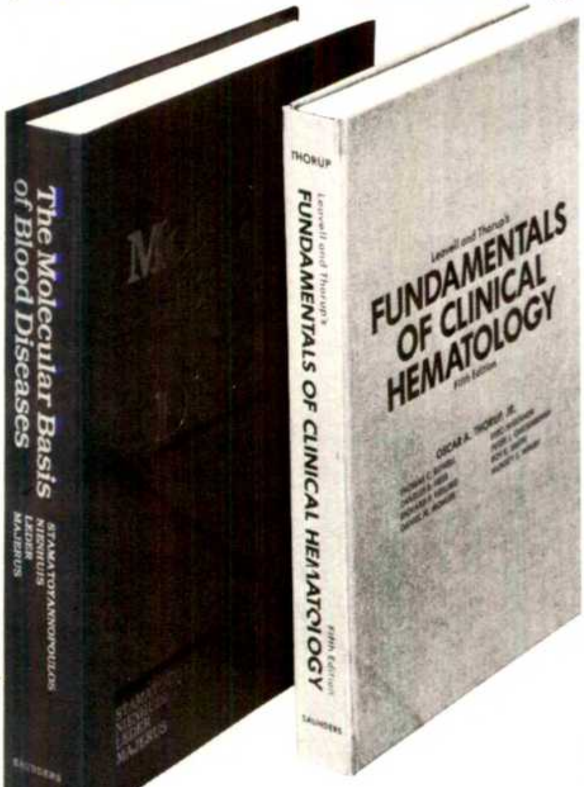
Essential Coverage Helps You Effectively Manage Hematologic Problems

Stamatoyannopoulos, Nienhuis,
Leder & Majerus
THE MOLECULAR BASIS OF BLOOD DISEASES

This new book focuses on general molecular and biochemical principles . . . and offers a detailed exposition of diseases for which the molecular basis has been established. They include hemoglobinopathies, coagulation factor deficiencies, inherited platelet function, thrombotic disorders, iron metabolism, AIDS, leukemias, and much more. Coverage of the techniques of molecular biology, specific neoplasms and oncogenes, the immune response system, and the molecular biology of hemostasis, thrombosis, and fibrinolysis is included as well.

By *George Stamatoyannopoulos*, MD, Prof. of Medicine, Medical Genetics, Univ. of Washington School of Medicine, Seattle, WA; *Arthur W. Nienhuis*, MD, Chief, Clinical Hematology Branch, National Heart, Lung, and Blood Inst., National Institutes of Health, Bethesda, MD; *Philip Leder*, MD, Senior Investigator, Howard Hughes Medical Inst., Chairman, Dept. of Genetics, Harvard Medical School, Boston, MA; *Philip W. Majerus*, MD, Prof. of Medicine and Biological Chemistry, Div. of Hematology-Oncology, Washington Univ. School of Medicine, St. Louis, Missouri. Over 765 pp. Over 525 ills. May 1987. $95.00. *W1373-X.*



Thorup
Leavell and Thorup's FUNDAMENTALS OF CLINICAL HEMATOLOGY,
5th Edition

This new, greatly expanded 5th Edition provides you with detailed coverage of hematologic disorders, their clinical manifestations, physiologic mechanisms, diagnostic methods, and details of treatment. Coverage includes cell function, morphology, blood and the lymphatic system, metabolic disorders of hemoglobin, classification, diagnosis, features of the anemias, and much more. Plus you'll find an outstanding new chapter on the **lymphomas** (both Hodgkins and non-Hodgkins); a new section on **nonmalignant disorders of lymphocytes** featuring superb, authoritative information on **AIDS**; and a new chapter on the **structure and function of the immune system** in health and disease. Over 300 illustrations highlight key concepts and methods presented to facilitate understanding.

By *Oscar A. Thorup*, Jr., MD, Prof. of Internal Medicine, Assoc. Dean, Univ. of Virginia, Charlottesville, VA. With 8 contributors. 1013 pp. 323 ills. May 1987. $75.00. *W5679-X.*

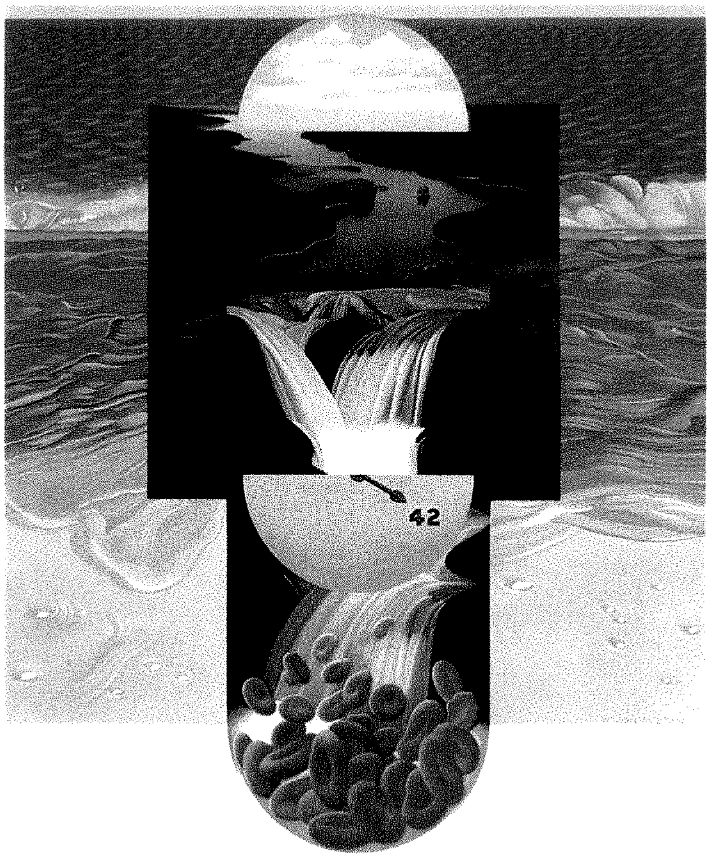
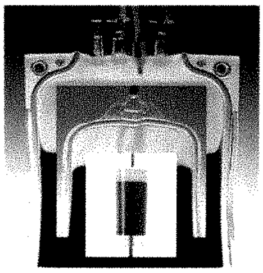
NOW YOU CAN STORE LEUKOPOOR RED CELLS



...WITH THE CUTTER LEUKOTRAP™ RED CELL STORAGE SYSTEM.

Now you can cost-effectively produce and store high-quality leukopoor red cells for *42 days*. The Leukotrap closed system efficiently removes leukocytes from fresh red cells, then maintains red cell viability for 42 days in the Nutricel® AS-3 additive solution.



Leukotrap's closed blood bag system contains an in-line leukocyte removal filter

MOST EFFICIENT CLOSED SYSTEM METHOD

The Leukotrap Storage System removes 91.4% of leukocytes and 80% of platelets, while recovering 90% of the red cells.*

SIMPLE, RELIABLE PROCEDURE

The Leukotrap System provides consistent results with only minimal technician time and a standard centrifuge.

Provide a better red cell product with the Leukotrap Storage System... another Component Enhancement Product, only from Cutter.

For more information, contact your Cutter Biological Representative or call our Professional Services Dept. at (800) 527-7200; in CA (800) 527-7222.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus*. (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

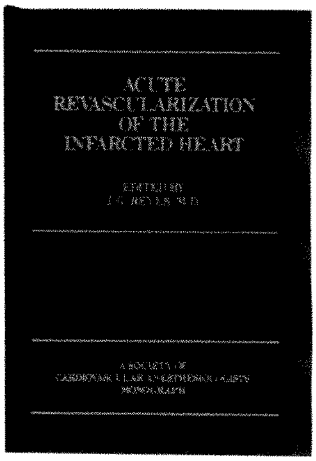
ACUTE REVASCULARIZATION OF THE INFARCTED HEART

Edited by

J. G. Reves, M.D.

Professor of Anesthesiology
Director, Division of Cardiothoracic Anesthesia
Duke University Medical Center
Durham, North Carolina

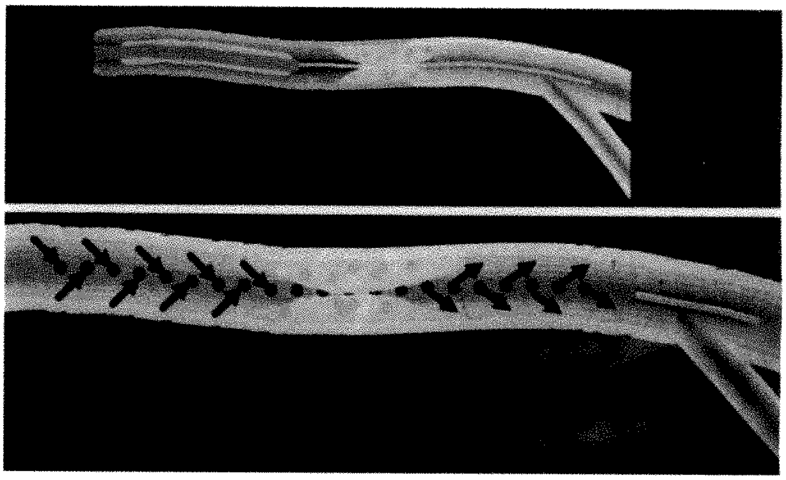
1987, 112 pp., $27.50/ISBN: 0-8089-1870-2, Order Code: 793531



Acute Revascularization of the Infarcted Heart presents the scientific basis for interventional therapy in patients with acute myocardial infarction.

The text's authoritative coverage is based on the new and unique concept of aggressive intervention. The opening chapter describes the scientific foundations for reperfusion. The role of surgical management and the use of emergency angioplasty for acute myocardial infarction are detailed. The anesthesiologist's role in the reperfusion of the acute myocardial infarction is also presented.

Cardiologists, cardiac surgeons, general practitioners, and anesthesiologists will appreciate the detailed coverage in this new book. The modes of intervention included and the presentation of results put *Acute Revascularization of the Infarcted Heart* in the forefront of current literature.



CONTENTS: *John H. Tinker,* The Scientific Foundations for Reperfusion of the Acutely Ischemic Myocardium. *Richard S. Stack,* The Management of Acute Myocardial Infarction Using Emergency Angioplasty. *Robert A. Kates, Russell Hill, and J. Chromogenics You Can Count On

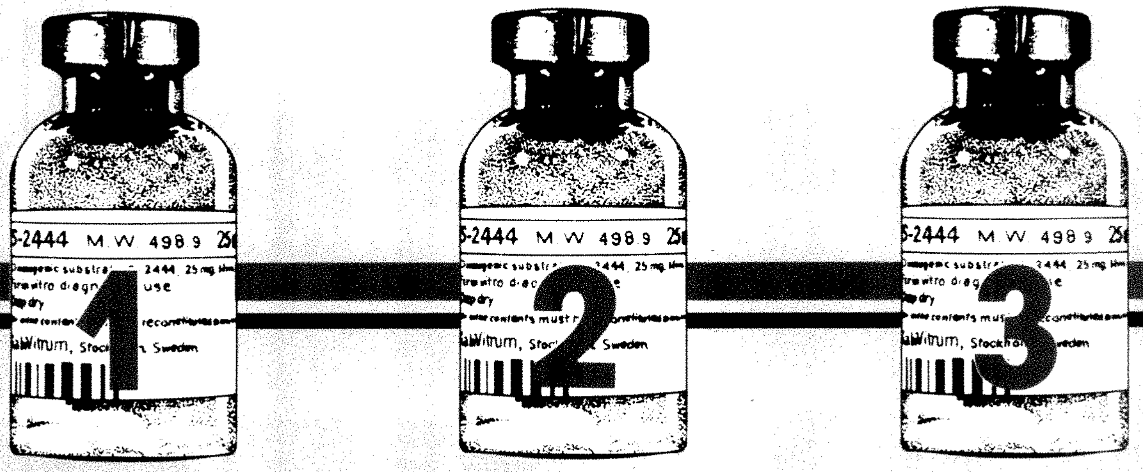
The reasons your lab should use KabiVitrum chromogenics are as simple as 1 2 3...



The First

The substrates you've been using all along were developed first by KabiVitrum. They pioneered the development of synthetic chromogenic substrates 10 years ago, and revolutionized the investigation of coagulation and fibrinolysis proteins. Years of experience enables KabiVitrum to produce the highest quality substrates available.

The Most

KabiVitrum's extensive product line ranges from S-2251 — the most widely used substrate in the world — to new products for tissue plasminogen activator and inhibitor assays. As exclusive U.S. distributor of KabiVitrum products, Helena provides immediate shipment of your order from our Texas headquarters. And we back these products with solid support from our customer service group.

The Best

KabiVitrum is committed to continued development of new substrates. Some of the new substrates available are S-2366, for activated protein C and Factor XIa; and thrombin inhibitor, I-2581. Soon you can expect substrates for α_2-macroglobulin, and α_1-antitrypsin.

Call for your free KabiVitrum catalog, or to place an order. Toll free U.S.A. 800-231-5663.
In Texas, 800-392-3126.
In Alaska, Hawaii and Puerto Rico, 800-231-4678.

HELENA HAS THE ANSWERS

A new rapid publication journal
for workers in clinical laboratory science

CLINICAL CHEMISTRY AND ENZYMOLOGY COMMUNICATIONS

Managing Editor: **Giorgio Federici**

Department of Biology, University of Rome "Tor Vergata",
Via Orazio Raimondo, Roma 00173, Italy

Call for Papers

Aims and Scope

Clinical Chemistry and Enzymology Communications aims to fill the need for rapid publication of new clinically based research in chemistry and enzymology relating to the diagnosis of human disease. It will feature papers, short communications and reviews on new findings and research. The journal's main areas of interest are enzymology, metabolism, toxicology, immunology, hematology, and analysis of body fluids or tissues. It will also publish papers on the development of new techniques and information about software for use in the laboratory.

Board of Editors

A. Burlina, Regional Centre for Clinical Enzymology, University of Padova, Via N. Guistiniani 2, 35128 Padova, Italy
W. Hohenwallner, Central Laboratory, Krankenhaus IV, Langgasse 16, 4010 Linz, Austria
E. Ishikawa, Department of Biochemistry, Medical College of Miyazaki, Kyotake, Miyazaki 889-16, Japan
K. Okuda, Department of Laboratory Medicine, Osaka City University Medical School, Abeno, Osaka 545, Japan
G. Siest, Centre du Medicament, UA CNRS 597, 30 rue Lionnois, 54000 Nancy, France

An Invitation to Contribute

The editors welcome the submission of communications in accordance with the aims and scope of the journal. Notes for Contributors may be obtained either from the editors or directly from Harwood Academic Publishers. Communications may be submitted to any member of the Board of Editors, or directly to the Managing Editor, who will arrange for their consideration.

First issue due early 1988

Radiogenic mucositis or herpes simplex?

See answer under flap. ▶

Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

ZOVIRAX® I.V.
(acyclovir sodium)

STERILE POWDER / I.V. INFUSION

When the problem begins with a virus, end it with an antiviral.

Please see following page for brief summary of prescribing information.

Both slides are herpes simplex
You may be surprised,
but especially in
immunocompromised patients
it is often difficult to
differentiate between herpes
infections and mucositis
resulting from radiation
therapy. Herpes simplex does
not always have a classic
presentation, and is easily
misjudged.

ZOVIRAX® I.V.
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax (acyclovir sodium) sterile powder is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS*** — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M^2 at a constant rate over 1 hour, every 8 hours (750 mg/M^2/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M^2)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

The journal will publish the description, technical and clinical evaluation of specific molecules and cell lines which may be used in the diagnosis, location and monitoring of disease.
Also to be included are the description of new or greatly improved strategies for the production of molecules or cell lines potentially suitable as probes and of new strategies for the generation and detection of signals from such probes. Animal studies in so far as they are clearly relevant as models or tests of techniques applicable to man also come within the scope of the journal. The journal aims to cross the traditional boundaries of diagnostic and clinical medicine departments since new probes or new approaches to the development of probes are likely to be of interest to workers in a variety of fields outside that of the original discoverers. By the publication of new work and reviews the journal will aim to keep readers in close contact with the most recent advances in this rapidly expanding area of medicine.

Research Areas Include:

- Detection and measurement of specific molecules by polynucleotides, monoclonal antibodies and cloned hybridomas or cell lines.
- Improved strategies for the production of these probes.
- Improved methods for the generation or detection of signals from these probes *in vivo* or *in vitro*.
- Animal models used as tests of the probes.

Blenoxane®
(sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain FI O_2 at concentrations approximately that of room air (25%) during surgery and the post-operative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

Heparin Binding Defect in a New Antithrombin III Variant: Rouen, 47 Arg to His

By M.C. Owen, J.Y. Borg, C. Soria, J. Soria, J. Caen, and R.W. Carrell

Antithrombin III (AT-III) Rouen is a hereditary abnormal antithrombin with normal progressive inhibitory activity and reduced heparin cofactor activity. It was isolated from the plasma of a woman who suffered a sudden idiopathic sensorineural hearing loss and balance impairment. There was no familial history of thrombosis. By heparin-Sepharose chromatography, AT-III Rouen was separated from the normal antithrombin on elution with increasing concentrations of NaCl. AT-III Rouen eluted earlier than is normal at both pH 7.4 and pH 6.0. At the lower pH, the antithrombins bound more avidly to the column, with the abnormal AT-III eluting closer to the normal than at the higher pH. Two-dimensional peptide mapping of tryptic and *Staphylococcus aureus* V8 protease digests of carboxymethylated antithrombins was performed on thin-layer silica plates. The abnormal peptide was located by tryptophan staining, and amino acid analysis and sequence studies demonstrated a substitution of an arginine at residue 47 for a histidine. Results from this study suggest that replacement of arginine 47 by a partially positively charged histidine has less effect on the heparin binding affinity than does replacing it with a neutral cysteine side chain as in AT-III Toyama, in which no heparin binding was observed. In addition, heparin binding per se is not a sufficient condition to activate AT-III.

© 1987 by Grune & Stratton, Inc.

ANTITHROMBIN III (AT-III) is a member of the serpin family of plasma protease inhibitors and is the major inhibitor of thrombin.[1] It is activated by heparin to increase dramatically its association rate with thrombin.[2] Reduced plasma AT-III activity predisposes to thromboembolic disorders. Conversely, as was seen with a unique mutation in a homologous protein, antitrypsin Pittsburgh, a high plasma antithrombin activity results in prolonged clotting times.[3] Although many variants of AT-III have been reported, to date only three have been fully characterized. They are one of two types, corresponding to two major functional sites of AT-III. The first and more common type involves amino acid substitutions in the heparin binding area such as are found with the variants, Toyama (47, Arg to Cys)[4] and Basel (41, Pro to Leu).[5] These mutations result in a decreased activation by heparin but do not affect heparin-independent or progressive thrombin inhibition. The second type are those that have substitutions in the reactive center loop as occurs in AT-III Denver (394, Ser to Leu).[6]

A heparin binding site involved in the mediation of the heparin activation of AT-III appears to be located at residues 41, 47, and 49.[4,5,7] The nature and extent of the heparin binding site and the mechanism of activation of the molecule by heparin are not known. Neither is it known whether binding and activation are necessarily linked, ie, whether binding can occur without activation or vice versa.

We describe in this article the characterization of a new AT-III variant, AT-III Rouen, in which the arginine at residue 47 is replaced by a histidine. This variant binds heparin less avidly than is normal and is incompletely activated by it, but has normal heparin-independent activity.

MATERIALS AND METHODS

Antithrombin-III assays. The plasma concentration of immunoreactive antithrombin was determined by the method of Laurell.[8] Functional studies were performed, with and without heparin, using synthetic chromogenic substrates of thrombin and factor Xa, according to the method described by Ødegard and colleagues[9] and Abildgaard and co-workers.[10] In the actual procedure the reagent kit of Diagnostica Stago was used (Asnières, France) with 0.3 mol/L of Tris pH 8.7 buffer containing 3 IU/mL of heparin.

Heparin binding and activation of AT-III. Studies on the relationship between heparin binding to and activation of normal and abnormal AT-III were performed with varying amounts of heparin using Chromozym TH (Boehringer, Mannheim, FRG) substrate in phosphate-buffered NaCl buffers at pH 7.4 at isotonic, two times isotonic, and four times isotonic ionic strengths. Typically,

to 600 μL of buffer containing 0.1 U, 5.0 U, or 50 U of heparin (mucous, Evans Medical, Liverpool, UK) and 0.5 μL of plasma 5 μL of thrombin was added (Parke Davis, Detroit, MI; topical bovine, diluted 15 μL to 1 mL). This was allowed to react for 20 minutes; 25 μL of substrate 5 mg/mL was then added, and the increase in absorbance at 405 nm was monitored.

Purification of AT-III. AT-III was isolated on heparin-Sepharose as described by McKay.[11] Typically, to 100 mL of plasma was added 1 mL each of 5 mol/L of $CaCl_2$ solution and 10% dextran sulphate (mol wt 500,000) solution. The supernatant was loaded onto a heparin-Sepharose column (1.5 × 30 cm), which was equilibrated with a buffer of 0.05 mol/L of Tris, 0.01 mol/L of citrate, and 0.15 mol/L of NaCl pH 7.4. The antithrombins were eluted with a linear NaCl gradient to 1.5 mol/L. Further purification was accomplished by ion-exchange chromatography on diethylaminoethyl (DEAE)-Sephadex A50 in 0.1 mol/L of Tris, 0.1 mol/L of NaCl pH 8.6, using a linear NaCl gradient to 0.45 mol/L.

Heparin-antithrombin binding at pH 6.0. The comparative binding to heparin-Sepharose of normal AT-III and Rouen at pH 7.4 and at pH 6.0 was investigated. The conditions above were used for the pH 7.4 experiment; however, at pH 6.0, a buffer consisting of 0.01 mol/L of sodium citrate and 0.01 mol/L of EDTA pH 6.0 was used.

Electrophoresis on agarose and sodium dodecyl sulfate polyacrylamide gels. Electrophoresis was carried out on 1% agarose gel at pH 8.6 in 0.075 mol/L of barbital buffer and at pH 6.0 in 0.01 mol/L of sodium citrate and 0.01 mol/L EDTA as described by Johansson.[12] Molecular weights were determined by electrophoretic mobilities in 7.5% sodium dodecyl sulfate (SDS) polyacrylamide gels according to the method of Laemmli.[13]

^{14}C-Carboxymethylation and proteolytic digestion. Typically, 5 mg of AT-III was dissolved in 1 mL of 0.3 mol/L of Tris pH 8.0 in 8 mol/L of urea. Ten microliters of dithiothreitol (10 mg/mL) sufficient to give a 2 molar excess over the thiol groups of AT-III was added, and the solution was flushed with nitrogen and left at room temperature for 5 hours. Five microcuries of ^{14}C-iodoacetic acid (Amersham, Buckinghamshire, UK) was added, followed 30 minutes later by a three fold excess of nonradiolabeled iodoacetic acid (0.4 mg). After a further 30 minutes, the labeled protein was dialyzed against distilled water.

Tryptic digestion was performed at pH 8.6 in 0.1 mol/L of ammonium bicarbonate with trypsin at 37°C for 2 hours. Digestion with *Staphylococcus aureus* V8 protease was made at pH 7.8 in 0.1 mol/L of ammonium bicarbonate for 18 hours at 37°C.

Peptide mapping. Essentially, the method of Powers and colleagues[14] was followed. Baker-flex (J.T. Baker Chemical, Phillipsburgh, NJ) silica gel 1B plastic backed 20 × 20 cm plates with a layer thickness of 200 μm were prewashed by being chromatographed overnight in pH 6.4 electrophoresis buffer, pyridine:acetic acid:water (200:8:1,800). After being dried and reactivated at 110°C for 30 minutes, 3 to 5 nmol of enzyme digest was loaded, and the plate was chromatographed overnight in *n*-propanol:ammonium hydroxide (7:3). The plate, after drying, was electrophoresed at pH 6.4 at 500 V for 50 to 90 minutes.

Peptides were located by being stained with fluorescamine (Hoffmann-La Roche, Basel) or cadmium-ninhydrin, and the Ehrlich stain was used for tryptophan-containing peptides.[15] ^{14}Carboxymethyl-cysteine peptides were identified by autoradiography for 4 to 8 days at −80°C.

Amino acid analysis was done on peptides located by fluorescamine.[16] A small area (1 × 3 mm) of the silica from the central region of the peptide was scraped off, and the peptide was extracted in 2 × 25 μL of pH 6.4 electrophoresis buffer and dried. After hydrolysis, the amino acids were derivatized with phenylisothiocyanate and analyzed according to the method of Bidlingmeyer[17] by reverse-phase high-performance liquid chromatography (HPLC).

HPLC peptide separations. Peptides were separated on a C-18 column (Waters radial compression module) in 49 mmol/L of phosphate pH 2.9 and eluted with an increasing percentage of acetonitrile. Peptides were collected, dried over nitrogen, and further purified and desalted by rechromatographing using 0.1% trifluoroacetic acid, eluting with an increasing acetonitrile concentration. Peptides thus isolated were used for sequence studies.

Peptide sequencing. Peptides were sequenced using the gas phase sequencing method on a model 470A protein sequencer from Applied Biosystems; the PTH-amino acids were identified by HPLC.[18]

Case report. A 40-year-old woman was admitted to the hospital because of sudden idiopathic sensorineural hearing loss and balance impairment. Laboratory studies showed that the plasma concentration of immunoreactive AT-III was normal (111% of normal pool), but the AT-III activity in the presence of heparin was reduced to 55% of normal as measured with the chromogenic substrate CBS 3447. Although there was no familial history of thrombosis, one of her two daughters, aged 14 years, also showed reduced AT-III activity.

RESULTS

In both the propositus and her daughter, the heparin cofactor activities were significantly reduced, being 55% and 62%, respectively, of a normal pool. The progressive antithrombin and anti-factor Xa activities were normal, as were the plasma antigenic levels of AT-III determined by electroimmunoassay (Table 1).

The results of heparin-Sepharose chromatography of the patient's plasma at pH 7.4 and pH 6.0 (Fig 1) show heterozygosity for an antithrombin of decreased heparin binding affinity. Normal AT-III eluted, at pH 7.4, with 0.8 mol/L of NaCl, and the abnormal protein eluted with reduced heparin affinity with 0.45 mol/L of NaCl. At pH 6.0, the normal AT-III eluted with 1.1 mol/L of NaCl and the abnormal protein eluted with 0.9 mol/L of NaCl. Hence, the difference in NaCl eluting concentrations between the two AT-IIIs at pH 7.4 (0.35) is significantly higher than at pH 6.0 (0.2).

The thrombin inhibitory activity at pH 7.4 of normal plasma and plasma from the propositus with varying amounts of heparin and ionic strength buffers is shown in Fig 2. Under all conditions, the inhibitory activity of normal AT-III exceeded AT-III Rouen. AT-III Rouen activity was preferentially impaired by low levels of heparin and high ionic strengths as compared with normal AT-III.

The mol wt of both proteins was identical at 56,000.

Table 1. Antithrombin-III Assays of Rouen Plasma Expressed as a Percentage of Normal Plasma

	Anti-IIa Activity		Anti-Xa Activity		Antigenic Level
	Hep Cof	Progr	Hep Cof	Progr	
Chromogenic substrate	CBS 3447	S2238	S2222	CBS 3139	
Propositus	55	—	—	120	111
Daughter	62	110	75	130	115

Hep Cof, heparin cofactor; Progr, progression.

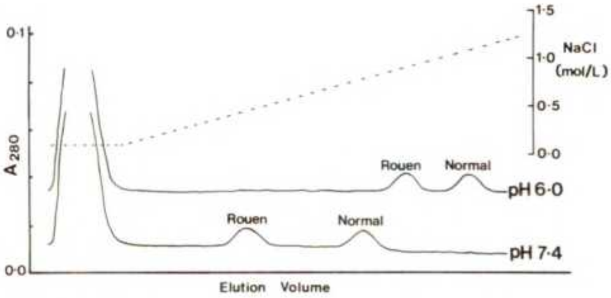

Fig 1. Elution profile of heparin-Sepharose chromatography of patient's plasma (heterozygous) showing the resolution of AT-III Rouen from normal antithrombin-III (AT-III) at pH 6.0 and pH 7.4. The proteins were eluted with an increasing linear NaCl gradient.

Electrophoresis on agarose gel showed the abnormal AT-III to migrate more anodally than the normal AT-III at pH 8.6, however, but to migrate essentially with the normal protein at pH 6.0 (Fig 3).

Numbers of peptide maps were prepared, and peptide analyses were performed to show only the one consistent difference, in peptides containing tryptophan 49. Maps of tryptic peptides revealed three tryptophan-containing peptides in the normal map but only two in the abnormal map. Amino acid analyses identified normal tryptic peptide 29 (residues 223 through 226) in both maps, but the identity and composition of the other two tryptophan peptides could not be conclusively determined because of contamination by neighboring or superimposed peptides. The V8 maps, however, gave two well-separated tryptophan peptides from both normal and abnormal proteins. A clear chromatographic shift and a minor electrophoretic shift had occurred in one of the peptides from the abnormal map. Amino acid analysis identified the peptide as residues 43 through 50 with, in the abnormal map, a histidine replacing one of the two arginines (Table 2). The sequence analysis of this peptide isolated by HPLC revealed that the arginine at residue 5 in the peptide was replaced by a histidine. This corresponds to position 47 in the intact protein.

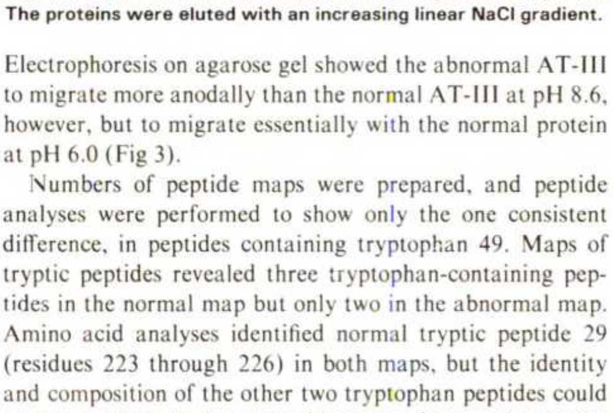

Fig 2. Antithrombin activity of control plasma containing only normal antithrombin-III (AT-III) (normal AT-III) and patient's plasma heterozygous for normal and Rouen AT-III in isotonic, two times isotonic and four times isotonic (the inhibitory activity of patient's plasma was below measurable limits) buffers in the presence of 0.1, 5.0, and 50 U of heparin. Results are expressed as a percentage of normal AT-III activity, which is caculated as the average activity for the three heparin concentrations of normal AT-III in isotonic buffer.

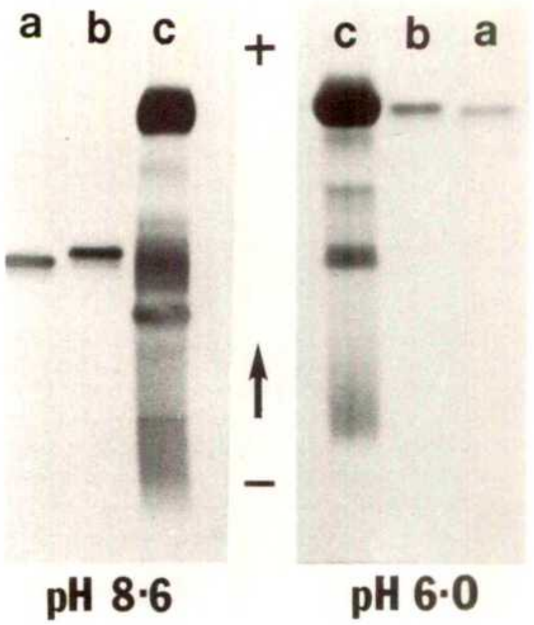

Fig 3. Electrophoresis in agarose gel at pH 8.6 and pH 6.0 of purified normal antithrombin-III (AT-III) (a), purified Rouen AT-III (b), and normal human serum (c).

DISCUSSION

We report here a new variant of AT-III, AT-III Rouen, that has decreased heparin binding affinity. The replacement of the normal arginine at position 47 by a histidine modifies the binding avidity for heparin at normal physiological pH. Whereas normal AT-III eluted with 0.8 mol/L of NaCl at pH 7.4, AT-III Rouen eluted at 0.45 mol/L of NaCl, a difference of 0.35 mol/L. At this pH, the histidine side chain would not be expected to be positively charged. This positive charge is likely to be restored to that which normally occurs with the arginine at position 47 when the pH is lowered to 6.0, which is below the usual pK_a of free surface histidine side chains in proteins.[19] This is demonstrated (Fig 3) by the electrophoresis at pH 6.0 at which the mobility of AT-III Rouen was essentially restored to that of the normal protein.

Table 2. Amino Acid Analysis of Tryptophan-Positive V8 Peptides (Arrows, Fig 5)

Peptide	Normal	Rouen
Asp	0.7	1.0
Glu	1.0	1.3
His	0.0	0.8
Arg	1.9	0.9
Thr	1.0	0.9
Ala	1.1	1.1
Val	0.8	0.7

Yield/residue = 65 pmol.

The difference in binding affinities between the normal and Rouen at this pH is indicated by the decrease in elution concentration to 0.2 mol/L of NaCl with the normal eluting at 1.1 mol/L and Rouen eluting at 0.9 mol/L of NaCl. Both antithrombins bind more tightly to heparin at pH 6.0 as compared with pH 7.4. Indeed, AT-III Rouen at pH 6.0 binds even more avidly than the normal at pH 7.4. Clearly, the reduction in the pH increased the overall protonation of the antithrombins, resulting in a stronger ionic attraction to the negatively charged heparin. AT-III Rouen, having an extra protonizable residue moves closer to the normal heparin affinity after the drop from pH 7.4 to 6.0.

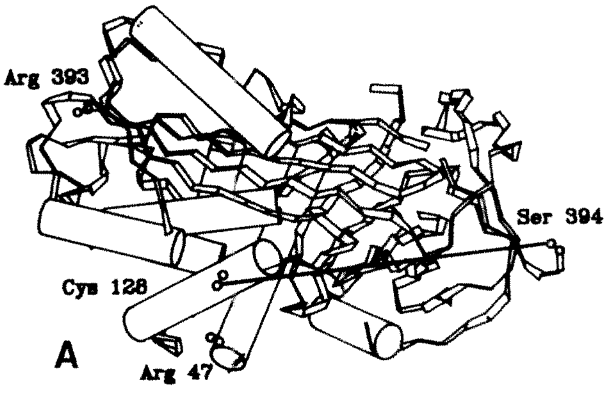
Yet, at pH 6.0, there still remains a difference in binding affinity between the protonated histidine 47 at AT-III Rouen and the normal AT-III. Because AT-III Rouen has an electrophoretic mobility essentially indistinguishible from normal AT-III at pH 6.0, incomplete protonation of the histidine seems unlikely. The results suggest that steric considerations are important and that heparin binding is not simply a charge effect. AT-III Toyama[4] is a mutant involving this same residue, 47, but has arginine replaced by a cysteine. Like AT-III Rouen, it has normal progressive activity but, although data were not given, Koide reported that AT-III Toyama has a total loss of heparin binding activity. This is surprising since in AT-III Rouen heparin binding is not solely dependent on this one residue. The new cysteine in AT-III Toyama forms a disulphide bond with free plasma cysteine,[4] and this may sterically block heparin binding.

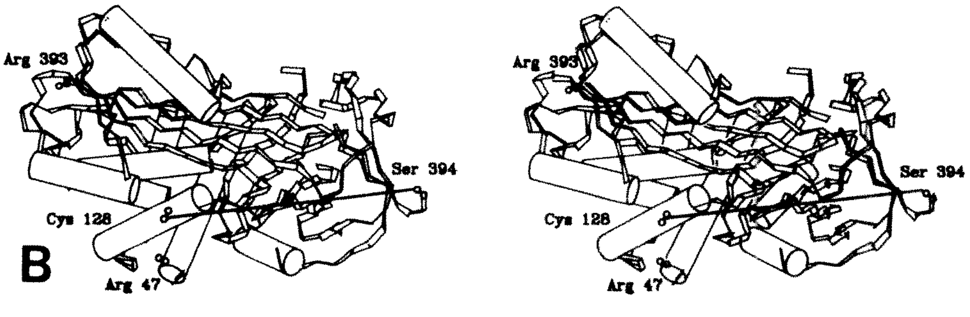
If the heparin binding of AT-III to the Sepharose-linked heparin reflects the binding in vivo, it seems clear that under physiological conditions AT-III Rouen still binds heparin, albeit less avidly than normal, but puzzlingly is not completely activated by the heparin. This raises the question of whether heparin binding per se is a sufficient condition to activate the molecule. The experiment assessing the activities of normal AT-III and AT-III Rouen at pH 7.4 in varying ionic strength buffers, with differing amounts of heparin, showed (Fig 2) that under normal isotonic conditions the plasma heterozygous for Rouen antithrombin averaged 73% of the activity of normal, whereas in twice isotonic buffer this dropped to 59%. At four times isotonic strength, AT-III Rouen was not measurably activated by heparin even at high concentrations. By comparison, normal AT-III was activated by the intermediate and high heparin levels but only to 12% and 24%, respectively, of the levels seen in normal isotonic conditions. The effect on activity of varying the heparin concentration was seen most dramatically in the two-times isotonic buffer in which the activity of AT-III Rouen increased 42% from low to intermediate heparin levels.

Hence, there is a competition between the charged heparin molecule and the buffer ions for the charged binding site regions on the AT-III. The normal AT-III with a greater heparin binding affinity can be fully activated with lower heparin levels than AT-III Rouen. Yet with high heparin levels and isotonic conditions, AT-III Rouen is not completely activated by the heparin binding. A distortion of the heparin binding site, although still enabling binding, may produce an effect distal to this site, resulting in misalignment of the heparin at some distant site and a consequent inability to activate the AT-III.

The mechanism of heparin activation of AT-III is still unknown. Recent homology studies[20] of the family of inhibitors to which AT-III belongs, the serpins, indicate that AT-III has substantially the same secondary structure as α_1-antitrypsin and hence has a similar tertiary structure. The crystallographic structure of post complex, cleaved, α_1-antitrypsin as determined by Loebermann and colleagues[21] is

Fig 4. Theoretical projection of antithrombin-III (AT-III) based on known structure of post-complex α_1-antitrypsin [(A) mono; (B) stereo]. Antithrombin has a flexible amino terminal tail of 45 residues hinged near the heparin binding site Arg 47. Heparin has been suggested to interact with this tail to reveal the active center (deduced[20,21] to be situated near Ser 394 in the intact molecule). The molecular model shows this to be unlikely because only seven residues of the tail are free to move from the cystine disulphide bond 8-128 allowing bridging of 27.2 Å v the minimum 35.38 Å (line from 128 to 394).





shown in Fig 4, with the structure of AT-III superimposable on it with only minor modifications. There must, however, be a significant structural difference between the two to explain the masking of inhibitory activity that occurs in AT-III but not in α_1-antitrypsin. The prime candidate is the N terminal tail of AT-III, which is longer than that of α_1-antitrypsin and has minimal homology with it. Furthermore, the mutation in antithrombin Rouen at Arg 47 is just past the base of the tail and the beginning of the first (A) helix. The longer N terminal tail of AT-III is held in its position on the external surface of the molecule by two disulphide bridges. The first one bridges residue 8 of the tail to residue 128, which is residue 14 of the D helix. The second bridges residue 21 of the tail to residue 95, which is sandwiched between the last residue of helix B and the first residue of helix C. This means that the N terminal tail must lie on the opposite side of the molecule to the deduced position of the reactive loop; thus, it is unlikely to shield directly or cover the reactive center of the molecule.

Further studies of this mutant and molecular characterization of variant antithrombins, particularly those of the class that have normal progressive activity but no heparin cofactor activity, should shed more light on the mechanism of heparin binding and activation of AT-III.

ACKNOWLEDGMENT

We wish to thank Dr M. F. Perutz and Dr P. George for helpful discussions, Dr D. Christie for the automated amino acid sequence studies, M. Sheat for technical assistance with agarose gel electrophoresis, and Dr. A. M. Lesk for preparation of Fig 4.

Clinical Investigation of Human Alpha Interferon in Chronic Myelogenous Leukemia

By Moshe Talpaz, Hagop M. Kantarjian, Kenneth B. McCredie, Michael J. Keating, Jose Trujillo, and Jordan Gutterman

Fifty-one patients with previously untreated or minimally treated chronic myelogenous leukemia in chronic phase received human alpha interferon 3 to 9 × 10^6 units intramuscularly (IM) daily until complete hematologic remission, then at doses ranging from 3 × 10^6 units every other day to 9 × 10^6 units daily. Forty-one (80%) patients achieved a hematologic response, 36 (71%) of them attaining a complete hematologic remission with normal peripheral WBC and differential counts. Responding patients showed continuous but slow normalization of several other blood and marrow parameters including platelet counts, serum lactic dehydrogenase and B12 levels, and marrow cellularity and maturation index. Suppression of the Philadelphia chromosome on serial cytogenetic studies of marrow metaphases was documented in 20 of the 36 patients who achieved complete hematologic remission (56%; 39% of total group), eight of whom (22%) had a decrease of the Philadelphia chromosome-positive metaphases to less than 35%. These changes were persistent for 6 months or longer in 18 patients, seven of whom had continuous suppression of the Philadelphia chromosome to less than 90% for a median of 30+ months (range 21+ to 39+ months). After a median follow-up period of 37 months, 25 patients remain in continued disease control with interferon therapy. The projected 3-year survival rate is 76%, with a yearly death rate of 6%, 9%, and 9% in the first 3 years. Response, Philadelphia chromosome suppression, and survival were significantly better among patients in the low-risk category compared to intermediate- and high-risk categories, as defined by a multivariate analysis-derived prognostic model. The projected 3-year survival rate was 94% for patients who achieved a complete hematologic remission on interferon therapy and 45% for those who did not. Thirteen patients have developed blastic crisis, six with lymphoid and three with undifferentiated morphology. We conclude that human leukocyte alpha interferon effectively controls chronic myeloid leukemia and allows reappearance of diploid hemopoietic cells in some patients.

© 1987 by Grune & Stratton, Inc.

CHRONIC myelogenous leukemia (CML) disease has a biphasic clinical course. The initial chronic phase is easily controlled with therapy and lasts for a median of 2 to 4 years. This then evolves into a phase of resistant, rapidly fatal blastic crisis.[1,2] Various therapies have resulted in significant but limited progress. The median survival after diagnosis has improved from 19 months for untreated patients[3] to a range of 30 to 45 months for those receiving single agents such as myleran or hydroxyurea[4-7] and 45 to 55 months for patients treated with intensive combination chemotherapy.[8-10] However, the progressive and ultimately fatal nature of CML has not been altered significantly; most patients still die from blastic crisis, with no consistent cure fractions recorded.[1,2,11] Allogeneic bone marrow transplantation is a promising approach in CML because of its curative potential, but its application and optimal timing are limited by donor availability, patient age, and the high incidence of morbidity and mortality in a disease that has a long chronic phase.[12] These factors emphasize the need for new modalities to treat patients with CML.

Interferons have opened new possibilities for managing patients with cancer.[13,14] Human alpha interferon (IFN-α), produced by virus-stimulated leukocytes, has undergone extensive trials and has shown promising results in several tumor categories including hairy cell leukemia and renal cell cancer.[15-17]

We have previously reported on our preliminary studies with IFN-α in CML showing its cytoreductive activity.[18] The activity of interferon in CML has also been documented recently using the pure recombinant alpha interferon material.[19] In this report we summarize our long-term results with the partially pure IFN-α in patients with Philadelphia chromosome-positive chronic-phase CML, evaluating efficacy and toxicity, describing the cytogenetic changes associated with therapy, and analyzing patterns of blast crisis, mortality rates, and overall prognosis.

PATIENTS AND METHODS

Population study. Between August 1981 and December 1984, 51 patients with Philadelphia chromosome-positive chronic-phase CML entered the study after giving informed consent. All patients were advised of procedures and attendant risks, in accordance with institutional guidelines, and gave informed consent. Eligibility criteria required the presence of less than 30% blasts in peripheral blood and bone marrow, absence of extramedullary disease, and minimal previous therapy. The patients' characteristics are detailed in Table 1. The median age was 42 years (range 20 to 70 years). The majority of patients had received no therapy, and 20 had been treated with single-agent chemotherapy for periods of less than a month. Forty-six patients (90%) started therapy within six months after the diagnosis. The patients' classification into low-, intermediate- and high-risk categories, based on a multivariate analysis model of pretreatment characteristics, was similar to that of the general CML population.[10] Forty-eight patients had the common 9;22 balanced translocation. Among these, two had evidence of disease acceleration with cytogenetic clonal evolution: one had additional chromosomal

material on the short arm of chromosome 16 (16p+) in 25% of the marrow metaphases; the other showed a balanced translocation between the long arms of chromosomes 8 and 17 [(t(8q−;17q+)] in 30% of marrow metaphases. The remaining three patients had Philadelphia-like translocations with the cytogenetic material being translocated between chromosomes 22 and 4 [t(4q+;22q−)], chromosomes 22 and 6 [t(6q+;22q−)], and chromosomes 22, 9, and 11 [t(9q;11p;22q)] in each, respectively.

Patient evaluation. Pretreatment evaluation included physical examination, complete blood counts (CBC), SMA 12, liver and renal function studies, determination of serum vitamin B12, lactic dehydrogenase (LDH) and leukocyte alkaline phosphatase (LAP) levels, bone marrow aspiration and biopsy, cytogenetic studies with Giemsa banding,[20] chest roentgenograms, and liver-spleen scan. Other studies were done as indicated by the patient's condition. Follow-up studies during the induction phase included physical examination and CBC two to three times weekly. After the cytoreductive results were observed, the frequency of studies was decreased to once every one to four weeks. A full workup, including bone marrow aspiration and biopsy, cytogenetic studies, vitamin B12 and LDH levels, LAP score and liver- spleen scan were done every 3 to 4 months during the first year and every 4 to 6 months thereafter. Serial cytogenetic studies were performed on at least 25 metaphases. If fewer than 25 metaphases were present in a particular specimen, a repeat bone marrow examination was done within one month. A marrow maturation index was defined as the ratio of the percentage of myelocytes, metamyelocytes, and granulocytes to the percentage of blasts and promyelocytes.

Treatment plan and dose modification. Induction therapy consisted of daily intramuscular injections of IFN-α (State Serum Institute, Helsinki, Finland) given at doses ranging from 3 × 10^6 units to 9 × 10^6 units daily until hematologic remission. For patients who achieved hematologic remission, the IFN-α dosage was reduced to levels varying from 3 × 10^6 units every other day to 9 × 10^6 units daily to maintain hematologic remission with a WBC count of less than 10,000/μL and a platelet count above 50,000/μL. Dosage modifications according to toxicity are detailed below.

Criteria for response, toxicity, and removal from study. Response criteria were defined as follows:

Complete hematologic remission: This required normalization of peripheral WBC counts to levels lower than 10,000/μL and normal differentials with no immature forms (blasts, promyelocytes, myelocytes, or metamyelocytes); normalization of platelet counts to less than 450 × $10^3/\mu L$; and disappearance of all clinical symptoms and signs of disease, including palpable splenomegaly. Maximal suppression of the Philadelphia chromosome was defined as four subgroups of (1) no cytogenetic response if the Philadelphia chromosome persisted in all analyzable metaphases, (2) minimal cytogenetic response if its expression was suppressed to percentages of 35% to 95%, (3) partial cytogenetic response if suppression was to levels of 5% to 34%, and (4) complete cytogenetic response if total elimination of the Philadelphia chromosome was noted in marrow metaphases.

Partial hematologic remission: This category was defined as a decrease in the WBC counts to at least 50% of pretreatment level and to at least below 20,000/μL; it included patients whose peripheral WBC counts had become normal but who had persistent splenomegaly or immature peripheral cells.

Failure: This group included all patients who had less than partial hematologic remissions.

Toxicity: Toxic reactions were graded as mild, moderate, severe, and life threatening on a scale of 1 to 4 (Table 2). The dose of interferon was reduced by 50% in patients with grade 2 toxicity. If toxicity persisted or was grade 3 or higher, interferon therapy was discontinued temporarily until the toxic effects reverted to grade less than 1. Grade 4 neurologic toxicity required permanent discontinuation of interferon.

Criteria for removal from the study. These included (1) development of blastic crisis with 30% or more blasts in the bone marrow or peripheral blood or the development of extramedullary disease; (2) failure to respond to therapy as evidenced by a continuous increase in WBC count or less than 25% decrease in WBC counts from pretreatment levels over a period of 14 weeks; (3) an initial response followed by subsequent increase in WBC count to more than 40,000/μL, uncontrolled by continued interferon therapy (patients with a cyclic peripheral leukocyte count pattern were continued on therapy unless the WBC counts were consistently higher than pretreatment values); and (4) unacceptable toxic reactions as defined above.

Statistical analysis. Survival and disease control duration curves were plotted by the method of Kaplan and Meier.[21] Disease control duration time was calculated from the date of start of therapy until development of resistance, toxicity, or blastic crisis. Tests of differences in survival distributions were based on a generalized Wilcoxon test.[22] Comparisons of differences among subgroups were made using chi-square tests for remission rates and degree of cytogenetic response.

RESULTS

Remission induction. All 51 patients in the study were evaluable with a median follow-up duration of 37 months. Induction therapy with IFN-α resulted in complete hematologic remission in 36 patients (71%). Five patients (10%) achieved a partial hematologic remission, three of these being classified as such because of persistent splenomegaly; and ten patients failed to improve (Table 3).

All 36 patients who obtained complete hematologic remission had, by definition, normalized peripheral WBC counts and differentials. The median time to achieve a complete hematologic remission was 14 weeks, with a range of 2 to 55

Table 2. Toxicity Criteria

Toxicity	1	2	3	4
Fever, chills, influenza-like symptoms; bone and muscle aches	Self-limiting, no therapy needed	Require antipyretics or anti-inflammatory agents	Require narcotics and/or hospitalization	Life threatening
Fatigue, performance status (Zubrod scale)	1	2	3	4
Weight loss (Percentage of body weight)	0-5	6-10	11-15	>15
Renal function (creatinine in mg/100 mL)		up to 2.5	>2.5	
Liver function				
Bilirubin (mg/100 mL)		up to 2.5	>2.5	
SGOT (mU/mL)		300-600	>600	
Neurologic	Does not interfere with daily activities or require medical intervention	Moderate impairment of activities, requires medical therapy	Severe impairment of activities, requires discontinuation of interferon and medical therapy	Coma, seizures, confusion, parkinsonism, severe depression
Hematologic				
Granulocyte count (per μL)		1,000-2,000	<1,000	
Platelet count ($\times 10^3/\mu$L)		50-100	25-50	<25

weeks. Two different patterns of response were observed. Twenty-six of the 36 patients (72%) had a steady gradual decline of peripheral counts and achieved remission after a median period of 9 weeks (range 2 to 28 weeks). The other ten patients (28%) manifested a cyclic pattern of response with WBC and platelet count in cycles of 4 to 8 weeks. Therapy induced lower peaks for WBC and platelet counts with each subsequent cycle; the median time to achieve remission in these patients was 26 weeks (range 8 to 55 weeks). Twenty-four of the 36 patients had had palpable splenomegaly that disappeared on follow-up studies. The responses of patients in each prognostic category were compared and are shown in Table 3.

Blood, marrow, and cytogenetic changes in patients who achieved complete hematologic remission. Changes in blood and marrow parameters in the first 2 years of therapy are shown for the 36 patients who achieved complete hematologic remission (Fig 1). Decline in WBC count was the earliest manifestation of response. Thrombocytosis with platelet counts of more than 500 × $10^3/\mu$L was present in 12 patients (33%), six of them having counts higher than 800 × $10^3/\mu$L. Platelet counts became normal in all responding patients. Subsequent increases in platelet as well as other parameters were noted among patients who failed after initial disease control, which accounts for the extreme values shown.

Serial bone marrow studies revealed a gradual decrease in bone marrow cellularity and an increase in maturation index. Marrow changes lagged behind peripheral blood changes: marrow cellularity declined from a median of 100% to a median of 75%, and the maturation index increased from a median of 8.3 before therapy to a median of 26.0 at 12 months (Fig 1).

Return of cells with diploid karyotype were noted with continued IFN-α therapy on serial cytogenetic studies of bone marrow cells. Twenty of the responding patients (56%, or 39% of the total group) manifested evidence of suppression of the Philadelphia chromosome on follow-up cytoge-

Table 3. Results of IFN-α Therapy

	No. of Patients in Risk Category* (Percentage)							
Response Category	Total		Low		Intermediate		High	
Complete hematologic remission	36(71)		18(82)		10(62)		7(64)	
Philadelphia status								
100%	16(31)		5(23)		3(19)		7(64)	
35%-95%	12(24)	39%	9(41)	59%	3(19)	44%	—	0%
5%-34%	3(6)		1(6)		2(13)		—	
0%	5(10)		3(14)		2(12)		—	
Partial hematologic remission	5(10)		2(10)		3(19)		—	
Resistant disease	10(20)		2(10)		3(19)		4(36)	
	51(100)		22(100)		16(100)		11(100)	

*Pretreatment characteristics were not available in two patients to determine their risk category: one had resistant disease, and one achieved complete hematologic remission but no suppression of the Philadelphia chromosome.

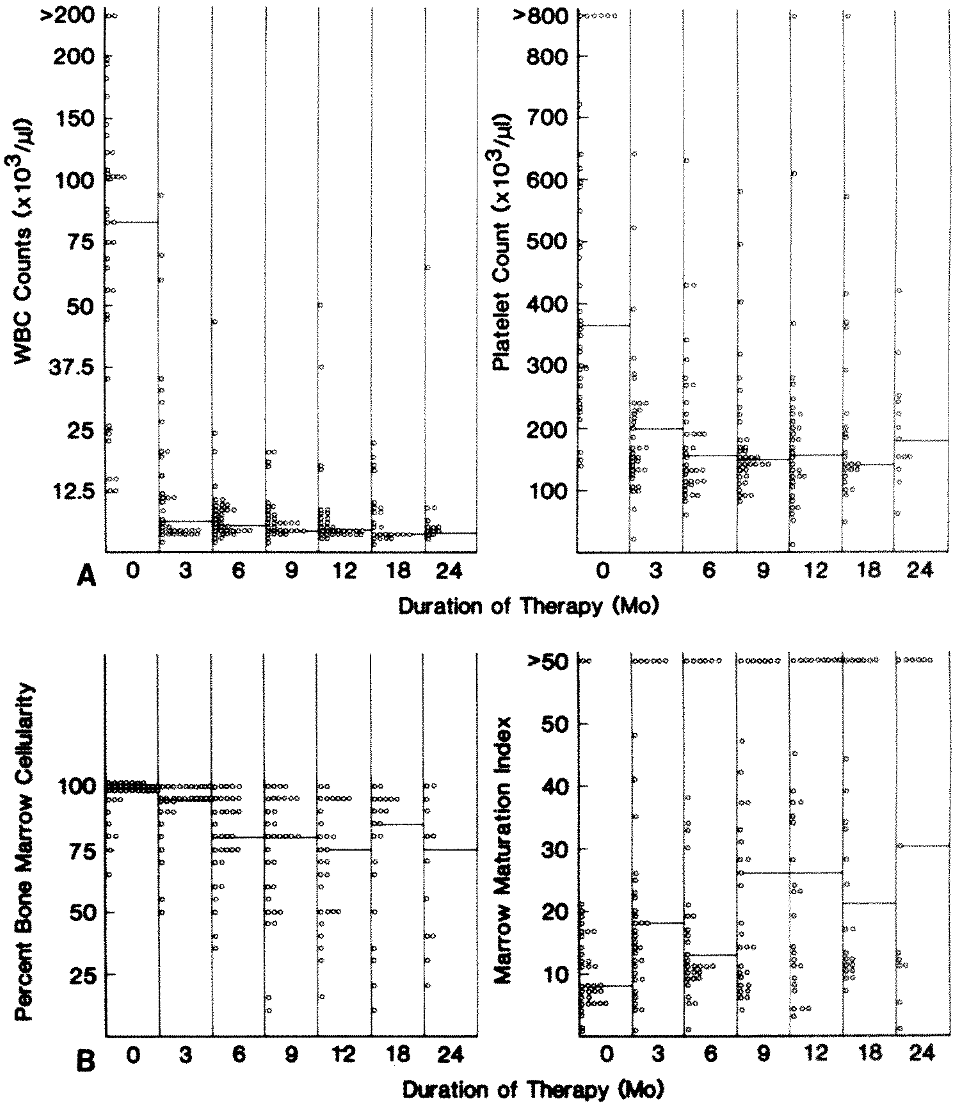

Fig 1. Changes in blood (A) and marrow (B) parameters with IFN-α therapy.

netic studies. Cytogenetic conversion to a partial diploid state was minimal (Philadelphia chromosome-positive in 35% to 95% of metaphases) in 12 patients (24%) and significant (Philadelphia chromosome-positive in less than 35% of metaphases) in eight patients (22% of responders, 16% of total). Suppression of the Philadelphia chromosome was slow, with changes observed after a median duration of 9 months of therapy (range 3 to 15 months). Cytogenetic conversion to a partial diploid state was short lived in two patients but persisted 6 months or longer in 18 patients, seven of whom showed evidence of continuous Philadelphia chromosome suppression for a median of 30+ months (range 21+ to 39+ months) (Table 4). The incidence of Philadelphia chromosome suppression was 59%, 44%, and 0% respectively, for low-, intermediate-, and high-risk groups ($P <$ 0.01) (Table 3).

Similar changes were documented for patients' serum LDH and vitamin B12 levels, which reverted slowly to normal values with response to therapy. Sixty-four percent of patients had had LDH values above 600 U/dL before therapy, compared to 12% after 3 months, 7% after 12 months, and 0% after 18 months of therapy. Similarly, although 94% of patients had had serum B12 levels above 1,000 pg/mL before treatment, this percentage decreased to 40% at 3, 25% at 12, and 14% at 18 months.

Disease control duration and failure patterns. The median duration of continued disease control with IFN-α was 29 months for the whole group (Fig 2), 33+ months for patients obtaining a complete hematologic remission, and 9 months for those achieving only a partial hematologic remission.

Patient outcome is summarized in Table 5. At the time of analysis, 25 of the initial 36 patients (78%) who obtained a complete hematologic remission remain in continued hematologic remission on IFN-α therapy, whereas 11 have failed: seven developed resistant disease and are all controlled on alternate therapies with hydroxyurea or myleran, and four evolved into blastic crisis. Of the 15 patients who achieved a partial remission or no response, ten were taken off the study while in benign phase (resistance 4, toxicity 1, both 5), four of them developed subsequent blastic crisis, two died in chronic phase, and four are alive on alternate treatments.

Table 4. Serial Cytogenetic Changes with IFN-α Therapy in 18 Patients with Persistent Philadelphia Chromosome Suppression for 6 or more Months

	Percentage of Philadelphia Chromosome-Positive Metaphases Months of Therapy										
Patient	3	6	9	12	15	18	21	24-27	30-33	36-39	42-45

15	100		100	100	90	45	95	90			
16	100	100	—	—	75	95	85	90			
17	100	IM	—	70	100	85	IM	85	100	100	100
18	100	80	75	90	100						

*IM = insufficient metaphases.

All but patient 18 are still on IFN-α therapy with continued disease control.

The other five patients who had partial remission or failed on therapy developed blastic crisis. Thus 11 of the 17 patients who showed resistance to interferon therapy in benign phase remain on alternative therapies with good disease control for a median of 20 months (range 12 to 35 months). Four developed subsequent blast crisis, and two other patients died, one of accelerated disease, the other of thoracocentesis-induced pneumothorax and empyema.

Thirteen patients have already developed blastic crisis after a median therapy duration of 11 months (range 2 to 30 months) (Fig 3). Blastic crisis has developed in 9 of the 15 patients who did not achieve a complete hematologic response compared to 4 of 36 who did (60% *v* 11%, $P < 0.05$). In the latter group three had no cytogenetic response, and one had a minimal cytogenetic response with a decrease of the Philadelphia-positive metaphases to 85% for 3 months only.

The patterns of blastic crisis and response to chemotherapy differed from previous experience. Six of the 13 patients had lymphoid blastic crisis, three had undifferentiated, and four had myeloid blast crisis morphologies. Five of the six patients who had lymphoid blast crisis achieved remission and entered a second chronic phase lasting for a median of three months (range 2 to 11+ months) with vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD).

Toxicity. Early and late patterns of host toxic reactions were observed among patients treated with IFN-α (Table 6). Forty-seven of the 51 patients (92%) experienced early toxic reactions, most of which consisted of fever, chills, fatigue, anorexia, and muscle and bone pains. Severe early toxic reactions were unusual and did not require interruption of treatment in any patient. Other toxicities such as insomnia, excessive sweating, nervousness, postnasal drip, and mild depression were unusual. The toxic effects usually lasted for a median of three days (range one to 12 days), improved gradually with therapy, and were manageable with antipyretic and analgesic medications.

The majority of patients tolerated chronic therapy well, with 76% maintaining an average performance status of 0 (Zubrod scale) and continuing their normal activities. Twelve patients (24%) had mild chronic symptoms with an average performance status of 1 to 2. Overall, six patients (12%) had treatment discontinued because of late toxicities.

Serious late toxic reactions included myalgias; bone and joint pains; severe fatigue, weight loss, and decreased performance; neurotoxicity; and immune-mediated thrombocytopenia (Table 6). The myalgias that occurred at some point during therapy in 17 patients were generally diffuse. Patients usually responded to a decrease in interferon dosage and to analgesics. Bone pains occurred most frequently in the proximal upper and lower extremities, pelvis, and ribs. Temporary discontinuation of therapy and administration of analgesics and steroids allowed therapy to be resumed in eight of the 12 patients who had severe pains. Chronic severe fatigue, anorexia, weight loss, and poor performance were observed in four patients.

Neurotoxicity was manifested in several patterns, some of which have been reported.[23] Central nervous system (CNS) manifestations consisted of apathy or agitation, insomnia, withdrawal, bland affect, lack of interest, decreased attention span and short-term memory, and depression. These occurred mildly in nine patients, improving with methylphenidate in six, and severely in three patients, requiring treatment interruption. One of the two patients who showed parkinson-like signs and symptoms had concomitant severe depression, which led to discontinuation of therapy.

Among the four patients who developed immune-mediated thrombocytopenia with platelet counts lower than 50,000/

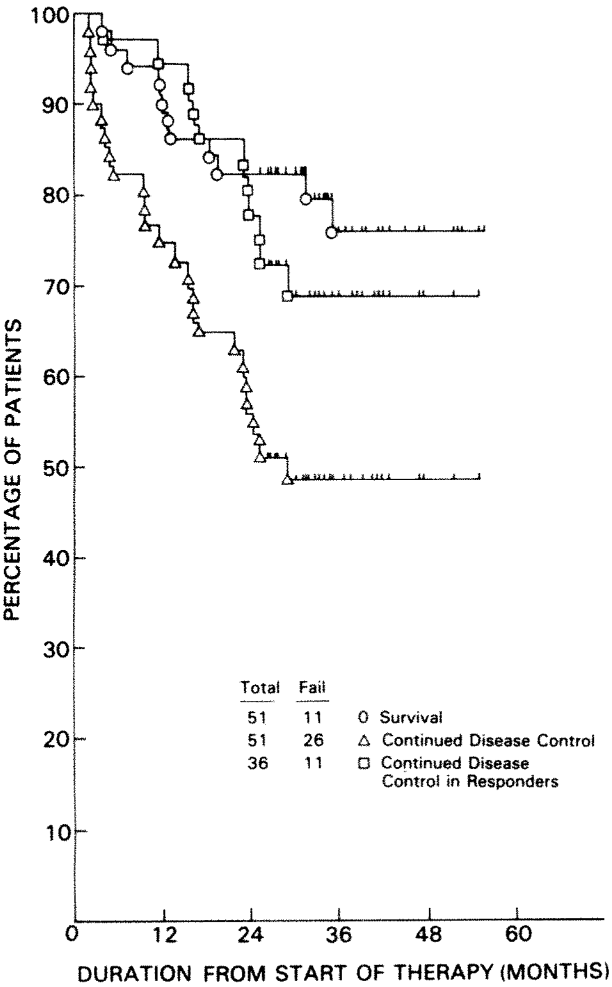

Fig 2. Duration of disease control and survival with IFN-α therapy.

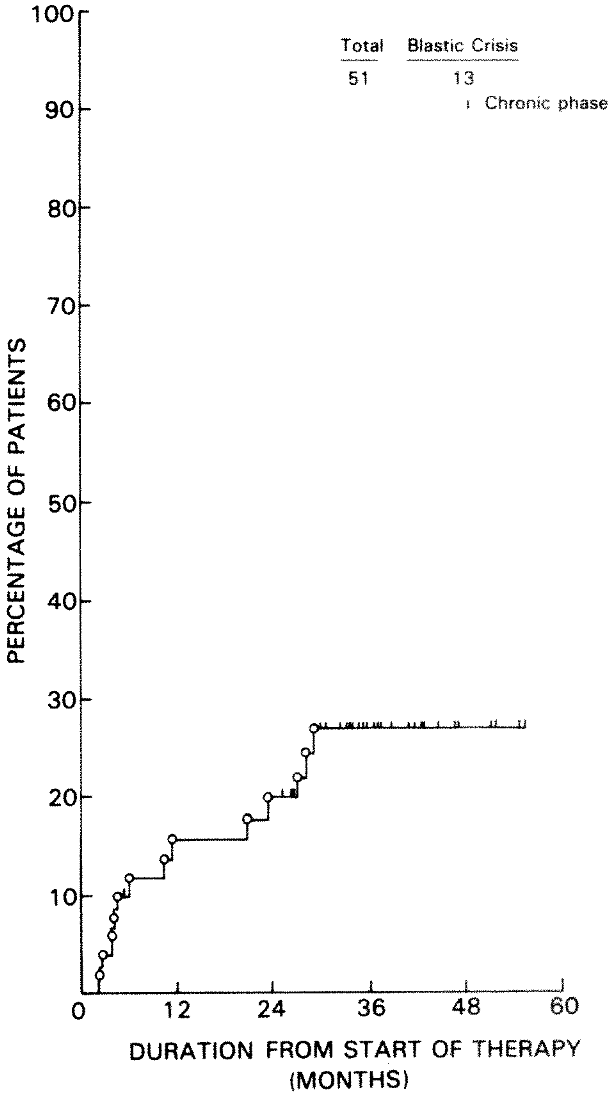

Fig 3. Cumulative incidence of blastic crisis in patients treated with IFN-α.

μL, platelet recovery was noted in two patients after discontinuation of interferon and institution of steroids; the other two patients underwent splenectomy for persistent thrombocytopenia with subsequent recovery of platelet counts. Other less common chronic toxic reactions included mild hair loss (18%), diarrhea (12%), headaches (14%), anorexia (10%), disturbed liver function (6%), postnasal drip (6%), cough, lung infiltrates, and impotence (2% each).

The incidence of severe toxic reactions increased with development of resistant disease. Five patients were taken off study because of resistant disease and increasing toxicity, which consisted of muscle or bone pains in four and neurotoxicity in one patient.

Table 5. IFN-α Therapy in CML: Present Status of Patients

	No. of Patients in Response Category (Dead)			
Status	Total	Complete Hematologic Remission	Partial Hematologic Remission	Resistant Disease
Continued disease control	25	25	0	0
Off therapy in benign phase	13 (2)	7 (0)	3 (0)	3 (2)
Blastic crisis	13 (9)	4 (2)	2 (2)	7* (5)
	51 (11)	36 (2)	5 (2)	10 (7)

*Includes four patients who discontinued therapy while in chronic phase and subsequently developed blastic crisis (see text).

Survival. After a median follow-up period of 37 months, 40 patients (78%) are alive, 36 being in chronic phase disease (25 of them on IFN-α therapy) and four in second chronic phase. The median overall survival has not been reached, and the projected three-year survival is 76% (Fig 2).

Relative yearly hazard rates for death were 6% during the first, 9% during the second, and 9% during the third year of study. The projected 3-year survival was 94% for patients with complete hematologic remission and 45% for those with partial hematologic remission or resistant disease. Only two of the 36 patients who achieved complete hematologic remission on IFN-α therapy have died, compared to 9 of the 15 patients who did not (6% v 60%; $P < 0.01$).

As with remission induction, different patterns of survival were observed in different risk categories: the 3-year survival

Table 6. Early and Late Toxic Reactions of IFN-α Therapy

Toxicity	No. Patients (Percentage)		
	Overall	Mild-Moderate	Severe
Early			
Fever	41 (80)	36 (71)	5 (10)
Chills	23 (45)	23 (45)	—
Bone pains	8 (16)	7 (14)	1 (2)

was 100% in the low-risk group, 75% in the intermediate-risk group, and 42% among the high-risk patients ($P < 0.01$).

DISCUSSION

Interferons have well-established antiviral and antiproliferative activities.[13] They were shown to suppress the growth and differentiation of normal and CML myeloid progenitor cells in vitro[24] and to induce granulocytopenia among treated patients.[15,17,25] The excessive myeloid proliferation in CML,[26] the possible viral etiology of CML shown in animal models,[27,28] and the success of interferon therapy for chronic or indolent diseases (hairy cell leukemia, renal cell cancer, indolent lymphomas and myeloma)[15-17] led us to investigate the clinical activity of IFN-α in CML.

The administration of human leukocyte IFN-α in the current study resulted in complete hematologic remission in the majority of patients. Therapy affected the peripheral blood, bone marrow, and spleen. The process of response was gradual, requiring a median of 14 weeks of therapy to achieve a complete hematologic remission and a median of 9 months to observe initial Philadelphia chromosome suppression. Changes were seen first in the peripheral blood, while bone marrow changes appeared late. A cyclic pattern of clinical response was observed in about one quarter of patients, possibly due to preservation of a partial feedback mechanism.[29,30]

Since our study used strict criteria in defining complete hematologic remission, the complete hematologic response rate of 71% is not comparable to response rates reported for myleran or hydroxyurea. Studies with these agents often did not require disappearance of palpable splenomegaly or complete normalization of the peripheral differential counts.[6,7]

Most interesting was the gradual suppression of the Philadelphia chromosome among responding patients. Previous studies with intensive combination chemotherapy resulted in significant suppression of the Philadelphia chromosome, with 30% to 60% of patients showing a decrease of Philadelphia chromosome-positive cells to less than 35%, and 10% to 30% manifesting 100% diploid metaphases.[8,31,32] These "true" complete and partial remissions were transient in all patients.[8,31] This demonstrates the existence of cells with a normal karyotype in the marrow of patients with CML that could repopulate the patient's marrow after eradication of the leukemic clones.[33,34] In contrast to the results of intensive chemotherapy, suppression of the Philadelphia chromosome-positive clones with IFN-α was slow to occur, progressive in nature, and long-lasting in a substantial number of our patients (Table 4). Suppression of the Philadelphia chromosome was also more pronounced among low-risk patients. The dramatic but transient cytogenetic response patterns with intensive chemotherapy and the slowly developing but persistent ones with IFN-α may be enhanced and maintained by the use of a combined modality approach.

The cost and scarcity of the partially pure human IFN-α material have been a significant problem in the conduct of large-scale clinical trials; this has been avoided recently through the availability of the pure recombinant alpha interferons. It has been argued that response to IFN-α or its toxicity may be partly attributed to the impurities of this partially purified form of interferon alpha. However, our recent preliminary experience with the pure recombinant alpha A interferon has demonstrated similar response and toxicity patterns.[19] Of the first 17 patients treated, 13 (76%) achieved a complete hematologic remission, and six (35%) had evidence of suppression of the Philadelphia chromosome.[19]

The chronic course of CML disease requires long-term follow-up to evaluate treatment benefit. One important question is whether IFN-α therapy will change overall patient prognosis. In this CML population, the yearly risk of death of 6% to 9% in the first three years compares favorably with the expected yearly mortality of 25% after the second year of follow-up for patients treated with single-agent therapy with myleran or hydroxyurea.[4-7] The 76% projected survival at 3 years is also encouraging in comparison with the 3-year survival rate of 53% among a historic control group of 155 patients from our institution who were treated with hydroxyurea or myleran[10] and with the 3-year survival percentage range of 35% to 65% in other reports.[1,2,4-7,11] The yearly incidence of blast crisis ranged from 5% to 15% in the first 3 years (Fig 3) and is lower than previously reported.[4-7] Interestingly, the majority of patients who developed blastic crisis manifested lymphoid or undifferentiated cellular morphologic characteristics. This contrasts with the reported 60% to 75% incidence of myeloid blastic crisis morphology reported in CML. This raises the possible advantage of additive chemotherapy in suppressing involved lymphoid cells. Finally, response to IFN-α seems to be a good parameter for predicting long-term prognosis. The 3-year survival rate was 94% for patients having a complete hematologic response and 45% for the remaining population.

The study of prognostic factors and risk categories in CML is useful in several ways,[10,35,36] including therapeutic strategy planning. Early intensive chemotherapy was shown previously to benefit mainly patients in the intermediate- and high-risk prognostic categories.[10] The present analysis demonstrates a substantial benefit of IFN-α therapy among intermediate- and low-risk patients. The combined use of intensive chemotherapy and interferons in a common treatment program may improve the outcome of all risk categories.

The acute toxic reactions to IFN-α were moderate. Chronic toxicities were treatment-limiting in 12% of patients. Serious toxicities included skeletal, muscular, and joint pains, neurotoxicity, and immune-mediated thrombocytopenia. Of interest was the simultaneous development of severe toxicity and resistant disease in a number of patients, raising the possibility of the release of certain factors from granulocytes that could induce inflammation in the musculoskeletal system.

In summary, this study showed IFN-α to induce hematologic remission in a majority of patients with chronic-phase CML. There were marked associated changes in the blood and bone marrow including suppression of the Philadelphia chromosome-positive clones. The unique biologic activity of IFN-α in CML opens possibilities for studies with interferons alone and in combination with intensive chemotherapy in an attempt to delay the onset of blastic crisis and to improve survival in this patient population.

An Analysis of Leukemic Cell Chromosomal Features in Infants

By Ching-Hon Pui, Susana C. Raimondi, Sharon B. Murphy, Raul C. Ribeiro, David K. Kalwinsky,
Gary V. Dahl, William M. Crist, and Dorothy L. Williams

Leukemic cell chromosomal findings in 27 infants were analyzed. Among the 18 cases of acute nonlymphoblastic leukemia (ANLL), all but two were classified as monocytic or myelomonocytic. The remaining nine cases were acute lymphoblastic leukemia (ALL), seven lacking the common ALL antigen and two having cytoplasmic immunoglobulin (pre-B phenotype). Twenty-five cases (93%) had an abnormal karyotype, 21 (84%) being pseudodiploid. Chromosomal translocations were detected in 67% of the ANLL cases and in 78% of the ALL cases. Nonrandom chromosomal abnormalities included the t(9;11)(p21-22;q23) in three cases of monocytic leukemia, inversion of chromosome 16 in three cases of myelomonocytic leukemia with bone marrow eosinophilia, and t(4;11)(q21;q23) in one case of ALL. Chromosomal regions preferentially involved in infant leukemia included 11q23-25 (13 cases), 9p21-22 (6) and 10p11–13 (3). All but one of the 24 cases with chromosomal breakage or rearrangement had breakpoints that corresponded to known fragile sites, half of which were at 11q23-25, a finding that may have pathogenetic importance. The CALLA$^-$ or pre-B phenotype and the presence of chromosomal translocations in most infants with ALL provide a biological explanation for their poor prognosis.

THE CLINICAL and biological hallmarks of acute leukemia in infants differ markedly from those of older children. Infants with acute nonlymphoblastic leukemia (ANLL) generally have acute monoblastic or myelomonoblastic subtypes with a propensity for extramedullary involvement.[1,2] Acute lymphoblastic leukemia (ALL) in infants is usually characterized by a large leukemia cell burden at diagnosis and by a blast cell immunophenotype that lacks the common ALL antigen (CALLA).[3-5] Treatment outcome tends to be poor in infants with either form of leukemia.[3,4,6]

Chromosomal abnormalities in leukemia have attracted much recent attention. The specific karyotypic patterns not only provide important prognostic information and allow more accurate classification, but also may aid in understanding leukemogenesis. Despite the known unique features of infant leukemia, cytogenetic studies in these patients have been limited to occasional case reports.[7] Because investigators tend to report nonrandom chromosomal changes such as the t(4;11),[8,9] little attention has been paid to the exact karyotypic distribution in cases of infant leukemia. In a relatively large series of consecutive cases of infant leukemia, we observed a high frequency of chromosomal translocations, which could explain the extremely poor prognosis associated with ALL in infants. Furthermore, our data suggest an unusual pathogenesis for acute leukemia in infants.

MATERIALS AND METHODS

Patients. From February 1979 to May 1986, 37 children aged <12 months with newly diagnosed acute leukemia were admitted to St. Jude Children's Research Hospital. Twenty-seven cases had adequate bone marrow samples and successful chromosome banding studies and are the subjects of this report. There were 18 cases of ANLL and nine of ALL. Informed consent was obtained for all patients, and the investigation was approved by the institution's clinical trials review committee.

Chromosome analysis. Bone marrow samples, obtained at the time of diagnosis, were processed according to the method of Williams et al.[10] Marrow cells were collected in RPMI 1640 medium with L-glutamine, antibiotics, and 30% fetal calf serum. The cells were immediately exposed to colcemid (final concentration, 0.06 μg/mL), rinsed twice in Hanks' balanced salt solution, and exposed to hypotonic KCl (0.075 mol/L) for a total of 32 minutes at room temperature, including periods of mixing, standing, and centrifugation. They were then fixed in 3:1 methanol-acetic acid (vol/vol) for 15 minutes, and slides were prepared by a flaming technique. Appropriate drying of the slides was achieved by natural aging for zero to seven days. Metaphase preparations were G-banded by a modification of the trypsin method of Seabright.[11] Chromosomal abnormalities were classified according to the International System of Human Cytogenetic Nomenclature (1985).[12]

Blast cell phenotyping. Cases of leukemia were classified according to French-American-British (FAB) criteria, based on bone marrow cell morphological and cytochemical staining characteristics.[13] Cases of ALL were further subtyped according to their immunophenotypes, as described previously.[14]

RESULTS

The presenting features, karyotypes, and treatment responses of the 27 infants with analyzable chromosomes are shown in Table 1. With two exceptions, the FAB types in cases of ANLL were either monocytic or myelomonocytic. Leukocyte counts for patients with ANLL ranged from 5.1 to 751 × 10^9/L (median, 63 × 10^9/L), platelet counts from 15 to 510 × 10^9/L (median, 71 × 10^9/L), and hemoglobin levels from 3.6 to 11.4 g/dL (median, 9.7 g/dL). Initial CNS leukemia was evident in ten patients. Bone marrow eosinophilia was noted in patients 11, 14, and 15 (18%, 15%, and 10% eosinophils, respectively); the first two patients had both

*Down's syndrome.

CNS leukemia at diagnosis and at relapse. Only six of these patients remain in remission, for 6+ to 47+ months.

CALLA$^-$, so-called undifferentiated (HLA-DR$^+$ only), ALL was diagnosed in seven infants and pre-B ALL (positive cytoplasmic immunoglobulin) in two, one of whom was CALLA$^-$. In case 20, two thirds of the blasts had L1 morphology, and the remainder resembled monoblasts, although the α-naphthyl butyrate esterase stain was negative. A lymphoid-associated antigen, B4, was present on 65% of blast cells and the myeloid-associated antigen My-9 on 39% of blasts. Leukocyte counts in cases of ALL ranged from 8.5 to 201 × 10^9/L (median, 90 × 10^9/L), platelet counts from 7 to 354 × 10^9/L (median, 42 × 10^9/L), and hemoglobin levels from 4.9 to 11.2 g/dL (median, 8.7 g/dL). Four infants had CNS leukemia at diagnosis; none had a mediastinal mass. Two of the nine patients remain in remission for 14+ and 26+ months.

Of the 18 cases of ANLL, 16 (89%) had leukemic cell chromosomal abnormalities (Fig 1). The most frequent structural abnormalities were translocations (12 cases, 67%), inversions (three cases), and deletions (two cases). Whole chromosome additions were noted in two cases, including patient 6 (a child with Down's syndrome); none of the cases showed a loss of whole chromosomes. The structural abnormalities most frequently involved chromosomes 11 (ten cases), 9 (five cases), 16 (four cases), and 10 (four cases). The chromosomal regions most commonly affected were 11q23-25 (seven cases), 9p21-22 (four cases), 11q12-13 (three cases), 16p13 (three cases), 16q22 (three cases), and 10p11-13 (two cases). Nonrandom chromosomal abnormalities included t(9;11)(p21-22;q23) in three cases of monocytic leukemia[15] and inversion at bands p13 and q22 of chromosome 16 in three cases of myelomonocytic leukemia with bone marrow eosinophilia.[16,17]

All nine infants with ALL had blast cell chromosomal abnormalities (Fig 2): pseudodiploidy in seven cases, hypodiploidy with 45 chromosomes in one, and hyperdiploidy with 47 chromosomes in one. Translocations were observed in seven cases (78%), of which six involved 11q23-25 and two involved 9p21.

In both ANLL and ALL, chromosomes 11, 9, and 10 were frequently involved in structural rearrangements, mainly translocations. The common breakpoints were 11q23-25 (13 of 27 cases, 48%), 9p21-22 (six cases, 22%), and 10p11-13 (three cases, 11%).

DISCUSSION

Chromosomal rearrangements involving 11q23-25 were the most frequent finding in this study of infant leukemia, affecting half of our patients. This contrasts with the much lower frequency of 11q23-25 rearrangements in consecutive cases of childhood ALL (4% of 230 cases) or ANLL (13% of

The abnormalities primarily involved chromosomes 9, 10, 11, and 16. The added chromosome 21 was from a child with Down's syndrome.**

150 cases) seen at our institution (DL Williams and SC Raimondi, unpublished observation). Similarly, Abe et al[7] and Abe and Sandberg[18] noted a higher frequency of such abnormalities in case reports of infants with leukemia. The high proportion of cases with the t(4;11)(q21;q23) in their series probably reflects a reporting bias, as these cases have a poor treatment outcome and unique features including mixed lymphoid and myeloid antigen expression.[19,20]

The other frequent abnormality involving 11q23 was t(9;11)(p21;q23), a nonrandom abnormality that is known to be associated with monocytic or myelomonocytic leukemia,[15] the two commonest ANLL subtypes in infants.[1,2] Case 21 [ALL with the t(9;11)(p21;q23)] is interesting in that most of the blasts appeared to be lymphoid, with a small proportion resembling monoblasts. The findings of both B4 and My-9 positivity in blast cells support the mixed-lineage antigen expression of her leukemia. Kaneko et al[21] also reported this chromosomal abnormality in two cases of CALLA$^-$ ALL, one of which occurred in an infant. Thus t(9;11)(p21;q23) is not only found in monocytic or myelomonocytic leukemia but also in CALLA$^-$ ALL, including some cases with mixed-lineage antigen expression. Rearrangements involving 11q23-25 are in general common findings in CALLA$^-$ ALL.[21] Some cases of CALLA$^-$ ALL are characterized by myeloid-associated antigens[22]; in others the blast cells have been induced to differentiate in the myeloid pathway.[23] Taken together, these findings support the idea of preferential transformation of pluripotent stem cells with 11q23 involvement in infants and suggest that genes from the reciprocally translocated chromosome influence subsequent phenotypic expression.[18,21] Recently we found an 11q23 translocation at relapse in each of several cases that had converted from common or pre-B ALL at diagnosis to CALLA$^-$ ALL (three cases) or ANLL (three cases) at relapse.[24] We have suggested that these cases represent emergence of a malignant pluripotent stem cell after eradication of the original B-cell precursor or pre-B leukemic stem line by chemotherapy.

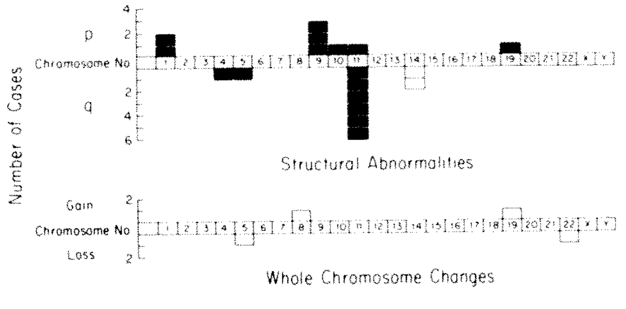

Fig 2. **Structural and numerical chromosomal abnormalities associated with acute lymphoblastic leukemia in infants. The closed blocks represent specific chromosomes involved in translocations and open blocks all other abnormalities. Each breakpoint is depicted once. Chromosomes 9 and 11 were frequently involved.**

Four of 29 cases of infant leukemia reviewed by Abe et al[7] had abnormalities involving chromosome 10, including three cases with a breakpoint at 10p11-13. Recently, another case of congenital monoblastic leukemia with del(10) (p12) was reported.[25] In this study four of 27 cases were found to have chromosomal abnormalities involving chromosome 10; in three cases the breakpoints were in the 10p11-13 region. By contrast, of 380 children with acute leukemia studied at this center, only five over a year of age had blast cell chromosomal rearrangement affecting this region ($P = 0.01$ by two-tailed Fisher exact test) (SC Raimondi and DL Williams, unpublished observation). Thus, the 10p11-13 region can be added to those known to be preferentially involved in infant leukemia.

The breakpoints in all but one of the 24 cases with chromosomal rearrangements (case 17) corresponded to known heritable or common fragile sites or both.[26-28] In 18 cases the breaks occurred at one or two heritable fragile sites, 13 being at 11q23 (FRA11B), five at 9p21 (FRA9A), three at 16q22 (FRA16B), and one each at 11q13 (FRA11A) and 12q13 (FRA12A). Confirmation of the putative association between heritable fragile sites and chromosomal breakpoints in infant leukemia will require further study of normal cells from the patients and their family members. Recently several studies have shown a concordance between heritable fragile sites and the breakpoints involved in chromosomal rearrangements in leukemia and lymphoma.[29-32] Hecht and Sutherland[33] found a statistically significant association between 21 fragile sites and 50 cancer breakpoints. It has been suggested that oncogenes or other very active genes may be located at or near hypersensitive or fragile sites where carcinogens can act, resulting in chromosomal breakage and rearrangement leading to malignant transformation.[27] Since infants are less likely than older patients to have experienced a carcinogenic event followed by a latency period adequate for the development of cancer, we speculate that acute leukemia in infants arises from constitutional or developmental genetic errors occurring at critical points in hematopoietic cellular ontogeny and differentiation.

Most of our cases had chromosomal breakpoint(s) where oncogene(s) have been mapped.[34] Since the c-*ets*-1 protooncogene has been traced to 11q23[35] and half of our cases have breakpoints in this region, it is possible that c-*ets*-1 is frequently involved in the pathogenesis of infant leukemia.

Rovigatti et al[36] have recently demonstrated amplification and rearrangement of this oncogene in a case of acute myelomonocytic leukemia and in a case of small lymphocytic-cell lymphoma with 11q23 involvement. It is also intriguing to note that α- and β-interferon genes have been localized to 9(p21 → pter),[37] a region commonly involved in infants with leukemia.

One of the most important prognostic factors in childhood ALL is age at diagnosis. Even after adjustment for other presenting features, a very young age remains an independent predictor of poor outcome.[38] However, in most studies leukemic cell chromosomal analyses have generally not been included, and their independent contribution to prognosis has not been assessed. In our most recent study,[39] the frequency of translocation was 40% among 116 consecutive children with newly diagnosed ALL. The high frequency (78%) of leukemic cell chromosomal translocations found in this study provides a biological explanation for the poor outcome of infants with ALL. Translocations in general appear to confer a poor prognosis in ALL.[40-42] The risk of early relapse was six times greater when a translocation was present, making this feature the strongest single predictor of outcome.[42] Notably, hyperdiploidy with >50 chromosomes, a favorable feature found in approximately 30% of childhood ALL cases,[39-44] was not found in any infant in this series or in the review by Abe et al.[7]

We conclude that most cases of infant leukemia are characterized by leukemic cell chromosomal abnormalities involving 11q23. The preferential involvement of 11q23 chromosomal region, the relationship between the breakpoints of reported fragile sites, and the likely minimal exposure of infants to environmental mutagens and carcinogens suggest a different mode of leukemogenesis in this young age group compared with older patients. Moreover, the poor outcome of infant ALL can be explained not only by their large leukemia cell burden and unfavorable immunophenotype but by the lack of leukemic cell hyperdiploidy and the frequent presence of chromosomal translocations. Finally, the definition of specific chromosomal anomalies in the blasts from infants with acute leukemia should provide direction for molecular studies that hold the exciting promise of unravelling the pathogenesis of these disorders.

Measurement of Platelet-Associated IgG in Animal Models of Immune and Nonimmune Thrombocytopenia

By Janice Arnott, Peter Horsewood, and John G. Kelton

Platelet-associated IgG (PAIgG) is elevated in idiopathic thrombocytopenic purpura (ITP), but it also is elevated in other thrombocytopenic disorders traditionally considered to be nonimmune. Consequently it is possible that elevated PAIgG is a nonspecific finding secondary to thrombocytopenia. To study this issue we developed a rabbit model of immune and nonimmune mediated thrombocytopenia. The mechanism of the thrombocytopenia was validated by platelet survival studies. Immune thrombocytopenia was produced by injection of antirabbit platelet serum that was raised in guinea pigs. Nonimmune aregenerative thrombocytopenia was produced by irradiation of the animals; nonimmune consumptive thrombocytopenia was produced by injection of adenosine diphosphate (ADP). PAIgG was measured in a direct binding assay using ^{125}I-labeled staphylococcal protein A (SpA). Washed platelets from normal, nonthrombocytopenic rabbits bound an average of 81 molecules of SpA per platelet (81 ± 168, mean ± 2 SD, n = 39). Infusion of the antiplatelet antiserum produced thrombocytopenia with a rise in PAIgG that was closely correlated with the level of PAIgG (r = 0.86, n = 12). The thrombocytopenia was consumptive, as shown by a very short platelet life span using ^{111}In-labeled platelets. In contrast, both nonimmune thrombocytopenic states resulted in an equal or greater drop in the platelet count but no change in the level of PAIgG. The animals with aregenerative thrombocytopenia had normal or only moderately reduced platelet life spans; however, in every animal the level of PAIgG was not different from the nonthrombocytopenic controls, irrespective of the platelet count. Similarly, the level of PAIgG was unchanged in those rabbits with nonimmune consumptive thrombocytopenia following infusion of ADP (82 ± 55 molecules of SpA per platelet, mean ± SD, n = 6). These studies indicate that elevated PAIgG is a specific finding of immune thrombocytopenia and is not secondary to thrombocytopenia itself. Indirectly these results support our hypothesis that immune mechanisms contribute to more thrombocytopenic disorders than was once thought likely.

FOR APPROXIMATELY 10 years, IgG on platelets has been measured qualitatively or quantitatively.[1,2] The amount of platelet-associated IgG (PAIgG) is elevated in about 90% of thrombocytopenic patients with idiopathic thrombocytopenic purpura (ITP).[3-6] This observation plus the demonstration that at least some of the IgG is specific for platelet glycoproteins[7] suggested that measurement of PAIgG could serve as a diagnostic test for ITP. However, PAIgG is also elevated in a large number of immune thrombocytopenic disorders, and consequently the test is not diagnostic for ITP.[8] Perhaps more importantly, elevated levels of PAIgG have been noted in a variety of disorders traditionally thought not to be caused by immune mechanisms.[8] These observations lead us to two postulates. First, they suggest that much of the IgG measured on platelets is not true autoantibody.[9] Second, the studies also suggest that immune mechanisms contribute to platelet destruction in more thrombocytopenic disorders than once was thought likely.[8]

It is difficult to study this issue in humans because many episodes of thrombocytopenia are associated with conditions such as sepsis and drug therapy, which by themselves might contribute to the thrombocytopenia.[8,10,11] For this reason we developed an animal model of three types of thrombocytopenia in rabbits: consumptive immune, consumptive nonimmune, and aregenerative nonimmune thrombocytopenia. When PAIgG was measured on washed platelets from animals with these various types of thrombocytopenia, we found that it was elevated in immune mediated thrombocytopenia but not in the nonimmune thrombocytopenias.

MATERIALS AND METHODS

Animal Studies

New Zealand white rabbits of either sex weighing 2 to 4 kg were used in all experiments. The animals were anesthetized with 30 mg/kg sodium pentobarbitol (MTC Pharmaceuticals, Hamilton, Ontario) administered intravenously (IV) through a marginal ear vein.

Preparation of Antiplatelet Serum

Antiserum against rabbit platelets was prepared in female guinea pigs. Whole blood from rabbits was collected into acid citrate dextrose (ACD, 6:1, vol:vol, pH 4.5), and the platelets were isolated by centrifugation, washed, and suspended in sterile saline. The guinea pigs were sensitized with an intraperitoneal (IP) injection of 10^9 platelets. Two further injections were given at one month intervals, and blood was collected, by cardiac puncture, at six days following the last injection. The serum was pooled and absorbed once (37°C for 60 minutes) with packed rabbit red cells (1:1, vol:vol) and once with washed rabbit lymphocytes. The serum was aliquoted and stored at −70°C until used.

The antiplatelet activity of the guinea pig serum was tested in vitro by two methods: enzyme-linked immunosorbent assay (ELISA) and radioimmunoprecipitation.

For the ELISA, rabbit platelets were isolated, washed three times, and resuspended to a concentration of 60,000/μL in 0.15 mol/L phosphate-buffered saline (PBS), pH 7.4. Fifty microliters of the platelet suspension was added to Immulon II (Dynatech, Alexan-

dria, VA) wells and centrifuged at 560 g for 13 minutes. The wells were incubated with a blocking buffer (0.2% gelatin, 0.1% sodium azide, 0.05% Tween, 0.15 mol/L PBS) overnight at 4°C and washed. Fifty microliters of test serum was added, and the wells were incubated at 37°C for one hour. After washing, 100 μL of staphylococcal protein A alkaline phosphatase conjugate (Boehringer Mannheim Canada Ltd, Dorval, Quebec) was added and the wells incubated at 22°C for 45 minutes. After four washes, 200 μL P-nitrophenyl phosphate disodium (Sigma Chemical Co, St. Louis) at 1.5 mg/mL in diethanolamine buffer (Sigma) was added and after a 30-minute incubation at 37°C, the reaction was stopped by the addition of 50 μL of 1 N sodium hydroxide. The optical density (OD) of the solution was read at 405 nm using a Microplate Autoreader (Bio-tek Instruments, Burlington, VT). A result was defined as positive if the OD was greater than two times the background OD.

For the radioimmunoprecipitation assay, rabbit platelets were isolated from platelet-rich plasma (PRP) by centrifugation at 2,200 g for ten minutes and washed twice in 10 mmol/L Tris, 10 mmol/L EDTA, 150 mmol/L NaCl, pH 7.4. The platelets were resuspended at 10^9 per mL in the same buffer and labeled with 1 mCi Na ^{125}I per mL using IODO-GEN (Pierce Chemical Co, Rockford, IL). The labeled platelets were washed and then lysed in 1% Triton X-100 (Biorad, Mississauga, Ontario), 10 mmol/L Tris, 10 mmol/L EDTA, 150 mmol/L NaCl, pH 7.4 containing 100 μg/mL leupeptin (Sigma) and 0.1 mmol/L phenylmethylsulfonylfluoride (Sigma). Radiolabeled platelet lysate plus 50 μL of the guinea pig antiplatelet serum was incubated at 4°C for two hours and then added to 50 μL of protein A Sepharose CL-4B beads (Pharmacia, Dorval, Quebec) for 30 minutes. The beads were washed in lysing buffer and the bound proteins eluted by boiling for three minutes in 60 mmol/L Tris-HCl, 2% sodium dodecyl sulphate (SDS), pH 6.8. The supernatant was added to the stacking gel of a 5% to 20% gradient SDS-polyacrylamide gel and run at 10 mA for 20 hours. The gel was stained with Coomassie blue and dried for autoradiography. Labeled proteins were detected with Kodak XRP-1 film after 24 hours of exposure.

Animal Models of Thrombocytopenia

Consumptive immune thrombocytopenia. Animals were anesthetized and infused with increasing amounts of antiplatelet serum through the marginal ear vein. AT 15-minute intervals, whole blood was sampled through a carotid cannula into EDTA tubes (Becton Dickinson, Mississauga, Ontario), and platelet counts were performed. At 90 minutes blood was collected into acid-citrate-dextrose (ACD) for determination of PAIgG. Control animals were infused with either normal (nonimmunized) guinea pig serum (NGPS) or 0.9% sodium chloride. All platelet counts were performed on a model ZBI Coulter electronic counter (Coulter Electronics, Hialeah, FL).

Consumptive nonimmune thrombocytopenia. Consumptive thrombocytopenia was produced by the infusion of 100 mg/kg adenosine diphosphate (ADP) (Sigma) through the marginal ear vein. Blood for platelet counts and PAIgG determination was collected through a carotid cannula at ten minutes after infusion. This time was selected as preliminary studies demonstrated that the platelet nadir had occurred by ten minutes. Because the platelet nadir occurred within ten minutes, the effects of multiple ADP infusions were also tested. ADP (80 mg/kg) was infused once daily for four days, and the platelets were then tested for PAIgG following the last infusion.

Aregenerative thrombocytopenia. Aregenerative thrombocytopenia was produced by irradiation of the rabbits with a ^{137}Cesium source (γ-radiation) for 30 minutes. This exposure to 930 rad produced thrombocytopenia at five to seven days. Blood was collected as previously described.

Measurement of platelet-associated IgG. Platelet-associated IgG was measured in a direct binding assay using staphylococcal protein A (SpA). SpA binds with the same relative affinity to both rabbit and guinea pig IgG.[12] Whole blood was collected into ACD, the platelets were isolated, washed three times in 0.15 mol/L PBS, 0.013 mol/L EDTA, 0.2% bovine serum albumin (BSA), and the platelet count was determined. Duplicate samples of 100 μl of platelet suspension were incubated with 25 μL of increasing concentrations (0.125 μg/mL to 10 μg/mL) of ^{125}I-labeled SpA (Amersham, Oakville, Ontario). After incubation for one hour at 22°C with agitation, the platelets were carefuly layered onto silicon oil (Dow Corning, Newbedford, MA) of specific gravity 1.022 and centrifuged at 12,000 g for three minutes. The radioactivity of the platelet pellet was measured. To distinguish specific binding from nonspecific binding, the same binding study was repeated with a 50-times excess of unlabeled SpA (Sigma).

The number of molecules of SpA bound per platelet was calculated as follows: specific binding was defined as the saturable binding of ^{125}I-SpA that could be displaced by the 50-times excess unlabeled SpA. The radioactivity at saturation was converted to molecules of SpA using the total number of platelets and the specific activity of the SpA.

Indium-labeled platelet survivals. One hundred milliliters of rabbit blood was collected into ACD. The platelet pellet was obtained by centrifugation of the PRP, and the pellet surface was gently washed five times with calcium-free Tyrode's buffer, pH 6.2. The platelets were resuspended in calcium-free Tyrode's buffer plus ethylene glycol tetra-acetic acid (EGTA) and labeled with 180 μCi ^{111}Indium oxine (Amersham). The labeled platelets were washed twice and resuspended in 1 to 2 mL platelet-poor plasma. The radioactivity associated with platelets and any contaminating red blood cells was determined as follows: one hundred microliters of the final labeled suspension was added to each of 2 mL of 1% ammonium oxalate and to 2 ml of 0.9% sodium chloride, and the suspensions were centrifuged. The platelet-bound radioactivity was calculated from the ammonium oxalate pellet, and the total cell-bound radioactivity was determined from the sodium chloride pellet.

The labeled platelets were infused IV through the marginal ear vein of recipient rabbits, and blood samples (3 mL) were collected into ACD at 30, 60, and 120 minutes postinfusion and once daily for five to seven days. To estimate the platelet life span, the radioactivity of whole blood samples was measured and the data was analysed by computer best fit using gamma function analysis.

To perform platelet survivals in the immune thrombocytopenic animals, labeled platelets were infused as described, but at 15 hours postinfusion antiplatelet antiserum was injected, and blood samples were taken at 30, 60, 180, and 300 minutes after the serum injection.

Statistical analysis. The means of platelet counts in the animal models were compared using an unpaired Student's *t* test at the 0.05 significance level.

RESULTS

Measurement of Platelet-Associated IgG on Rabbit Platelets

The percent recovery of platelets through the silicon oil was validated using ^{51}Cr-labeled platelets. At the specific gravity of 1.022 used, greater than 95% of the platelets crossed the gradient. Over a platelet concentration of 60,000 to 1,000,000 platelets/μL, recovery was consistently greater than 95%.

Since ADP infusion may cause a decrease in the mean platelet density of circulating platelets, the passage of these platelets through oil was validated in the same way. Platelets from ADP-treated animals were labeled with ^{51}Chromium and passed through silicon oil (specific gravity, 1.022). Over a platelet concentration of 300,000 to 1,000,000 platelets/μL, recovery was equal to or greater than 99%.

Sizing experiments performed on ADP-treated platelets using a particle sizer and stained blood film showed them to be of normal size with no fragments.

Normal, nonthrombocytopenic rabbits bound 81 ± 168 molecules of SpA per platelet at saturation (mean ± 2 SD; n = 39 different rabbits). A representative binding curve is shown in Fig 1.

Platelet Survival Studies

The in vivo recovery of the radiolabeled platelets was defined as the percent radiolabeled platelets in the circulation at two hours postinfusion and was always greater than 75%. The mean platelet-associated radioactivity was 82%, and on average there was 4% red cell contamination. The average platelet life span of nonthrombocytopenic rabbits as determined by gamma function analysis was 68 ± 23 hours (mean ± SD; n = 15) (Table 1).

Consumptive Thrombocytopenia (Immune)

The antiplatelet activity of the serum was confirmed by the ELISA and the radioimmunoprecipitation assay. Normal (nonimmunized) guinea pig serum did not bind to rabbit platelets and gave a mean OD of 0.158 in the ELISA (n = 3). However, the immunized guinea pig serum reacted strongly with rabbit platelets, producing an OD of greater than 1.50 neat and an OD of 0.809 at a 1:128 dilution in buffer (n = 3).

The antisera was further tested using a radioimmunoprecipitation assay. The immune serum contained IgG antiplatelet antibodies that reacted with a large number of rabbit platelet glycoproteins as shown in Fig 2.

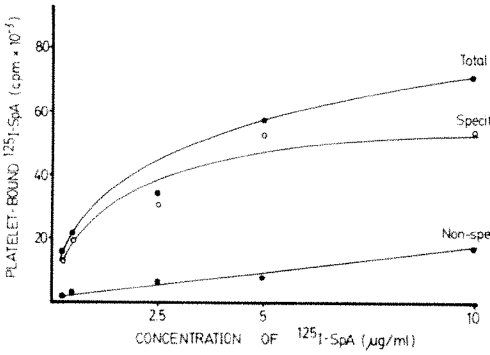

Fig 1. A typical binding curve for the PAIgG assay. Washed platelets from an antiserum-injected rabbit were incubated with increasing concentrations of ^{125}I-labeled SpA (abscissa), plotted against the radioactivity of the platelet pellet (ordinate). Specific binding is the saturable binding of ^{125}I-labeled SpA that is displaced by the 50-times excess unlabeled SpA and is calculated by subtraction of "background" nonspecific binding from total binding.

Table 1. ^{111}In-Oxine Platelet Survivals

Treatment of Rabbits	n	Platelet Life Span (hours)	Range (Hours)
Normals	15	68 ± 23*†	32.3-103
Aregenerative thrombocytopenia	10	30 ± 17*†	11.1-63.2
Consumptive immune thrombocytopenia	3	0.20	0.17-0.23

*Mean ± SD.

†Gamma function analysis.

Platelet counts and PAIgG determinations were performed on sham-treated (0.9% sodium chloride) rabbits and rabbits injected with normal guinea pig serum. In these animals the mean post-treatment platelet count was not significantly different from the mean platelet count of normal rabbits, and the PAIgG was within the normal range at a mean of 45 molecules of SpA per platelet (range 9 to 136 molecules SpA per platelet, n = 12).

Infusion of the antiplatelet antiserum produced an immediate consumptive thrombocytopenia. The mean platelet count for these animals differed significantly from that of normal, nonthrombocytopenic animals ($P < 0.05$), (Fig 3B). In every rabbit given the antiplatelet antiserum, the level of PAIgG rose to a mean of 2,400 molecules SpA per platelet (range 815 to 4,330 molecules SpA per platelet, n = 12), (Fig 3A). The rise in PAIgG and the fall in the platelet count were both strongly correlated with the amount of antiserum administered. The severity of the thrombocytopenia correlated significantly with the level of PAIgG (r = 0.86, n = 12), as shown in Fig 4A. Similarly, the level of PAIgG

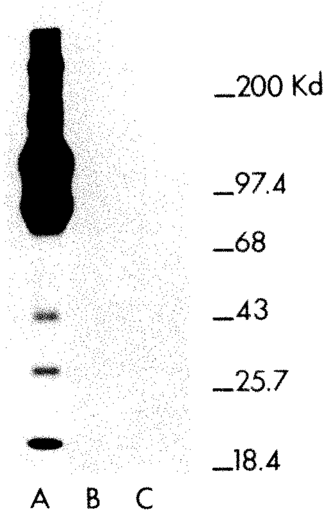

Fig 2. An autoradiograph of the radioimmunoprecipitation assay using ^{125}I-labeled rabbit platelets and the guinea pig antirabbit platelet serum. This serum reacted with a large number of rabbit platelet glycoproteins (lane A). Normal guinea pig serum (lane B) and saline (lane C) did not precipitate any proteins.

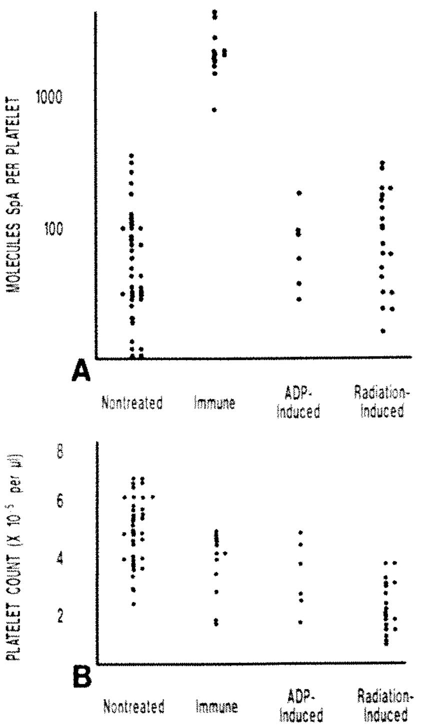

Fig 3. (A) Molecules of SpA per platelet in the immune and nonimmune thrombocytopenic animals. PAIgG, expressed as molecules of SpA per platelet, is plotted on semilogarithmic paper (ordinate) against nontreated and thrombocytopenic rabbits (abscissa). (B) Platelet counts in the immune and nonimmune thrombocytopenic rabbits. The platelet count (ordinate) is shown for nontreated and thrombocytopenic rabbits (abscissa). The mean platelet count for the nontreated rabbits is significantly higher than the mean platelet counts for the thrombocytopenic rabbits ($P < 0.05$).

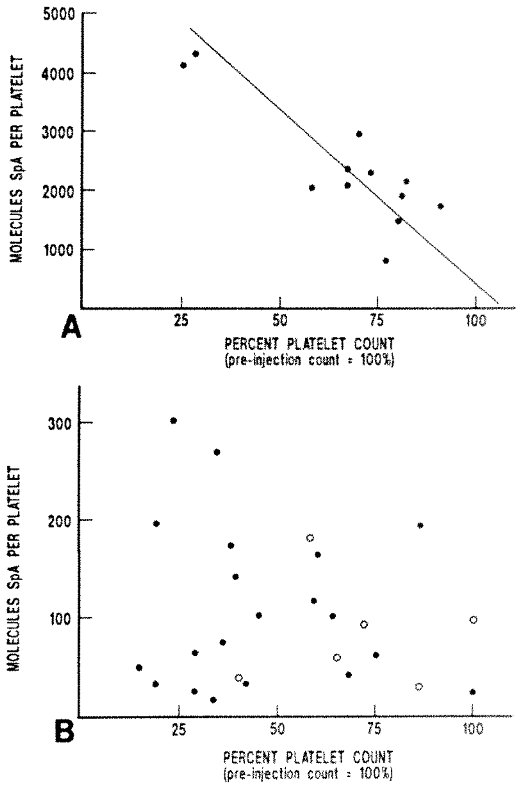

Fig 4. (A) PAIgG plotted against the platelet count in the immune thrombocytopenic rabbits. There was a significant correlation ($r = -0.86$, $n = 12$) between the PAIgG (ordinate) and the platelet count (abscissa). (B) PAIgG plotted against the platelet count in the ADP-treated (○) and irradiated (●) rabbits. There was no correlation between the PAIgG (ordinate) and the platelet count (abscissa) for the ADP-treated rabbits ($r = -0.02$, $n = 6$) or for the irradiated rabbits ($r = -0.13$, $n = 20$).

was directly correlated with the amount of antiserum injected ($r = 0.94$, $n = 12$).

Platelet survival studies were performed on the antiserum-injected animals. Following infusion of the antiplatelet antiserum, approximately 80% to 90% of the platelets were lost from the circulation within 30 minutes (Table 1).

Consumptive Thrombocytopenia (Nonimmune)

Infusion of ADP resulted in a significant fall in the mean platelet count ($P < 0.005$) in comparison with nontreated animals (Fig 3B). However, in contrast to the animals with immune thrombocytopenia, all of the rabbits with nonimmune consumptive thrombocytopenia caused by ADP infusion had levels of PAIgG that were within the normal range at 82 ± 55 molecules of SpA per platelet (mean ± SD, $n = 6$), (Fig 3A). In these animals there was no correlation between the platelet count and the level of PAIgG (Fig 4B). In the animals treated with multiple ADP infusions, the level of PAIgG remained within the normal range at 78 ± 26 molecules of SpA per platelet (mean ± SD, $n = 4$).

Aregenerative Thrombocytopenia

Irradiation of the rabbits resulted in platelet counts that were significantly lower than the mean for normals ($P < 0.0005$) (Fig 3B). In every one of these animals the PAIgG level remained within the normal range at 109 ± 84 molecules SpA per platelet (mean ± SD; $n = 20$), as shown in Fig 3A. In these animals there was no correlation between the platelet count and the level of PAIgG (Fig 4B).

The radiation-treated animals had a platelet life span that was normal or marginally reduced (Table 1).

DISCUSSION

Techniques for detecting IgG on platelets have been available for a number of years and have been used to investigate many different thrombocytopenic disorders. There is now general agreement that the level of platelet-associated IgG (PAIgG) is increased in about 80% to 90% of thrombocytopenic patients with idiopathic thrombocytopenic purpura.[2-4] The recent demonstration that antiplatelet antibodies in the serum of patients with ITP bind to platelet-specific antigens via the F(ab) terminus of the antibody molecule indicate that at least some of the IgG on the platelet surface represents true autoantibody.[7] However, a number of studies from our laboratory have raised several issues that are as yet unresolved. For example, our demonstration that the increase of platelet-associated IgG is paralleled by an increase in platelet-associated albumin suggests that much of the increased platelet-associated IgG is not true autoantibody.[9] In addition, platelet-associated IgG is elevated not only in typical "immune" thrombocytopenic disorders but also in many disorders traditionally not considered to be caused by immune mechanisms.[8] Taken together these observations have several possible interpretations: first, elevated levels of platelet-associated IgG might in part be due to artifacts of the test system, for example, contaminating platelet fragments. Recent studies suggest that this is an unlikely explanation.[13] Another possible reason for the elevated levels of platelet-associated IgG in nonimmune thrombocytopenic disorders is that the thrombocytopenia by itself could lead to elevated levels of platelet-associated IgG (the opposite of what is currently postulated). The studies described in this report were designed to address this issue. We studied animal models of thrombocytopenia because it is difficult to study "pure" thrombocytopenic disorders in humans. Typically, patients with one type of thrombocytopenia, for example, aplastic anemia, have thrombocytopenia that is complicated by other conditions, such as septicemia, which makes it difficult to isolate a single cause for the thrombocytopenia.

To investigate the relationship between the platelet count and the level of PAIgG, thrombocytopenia was produced in rabbits using several different techniques. The general mechanism responsible for the thrombocytopenia was validated with ^{111}Indium-labeled platelet survival studies. The life span of ^{111}Indium-labeled platelets in normal, nonthrombocytopenic rabbits was 68 hours (gamma function analysis), a finding similar to that reported by others.[14] Independently, the level of PAIgG was measured with a direct binding assay. The "positive control" was an animal model of immune thrombocytopenia. IgG antirabbit platelet antibody was raised in guinea pigs and was demonstrated by both ELISA and radioimmunoprecipitation (Fig 2) to react in vitro against a number of different glycoproteins. Following infusion of the antiserum into rabbits, a rapid destructive thrombocytopenia resulted, and greater than 80% of the ^{111}Indium-labeled platelets were cleared from the circulation within 30 minutes after infusion. The fall in the platelet count was strongly correlated ($r = 0.89$) with the amount of serum injected. Thus we were able to conclude that the binding of the antibody to the rabbit platelets was responsible for the thrombocytopenia. The amount of PAIgG on the rabbit platelets was measured with a direct binding assay using radiolabeled staphylococcal protein A (SpA) as the ligand. Staphylococcal protein A binds equally well to both rabbit and guinea pig IgG.[12] To measure PAIgG on washed rabbit platelets, the specific binding of the ^{125}I-SpA to the washed platelets was measured in the standard fashion with subtraction of background nonspecific binding from total binding. The amount of PAIgG was expressed as molecules of staphylococcal protein A per platelet because the binding ratio of the SpA to platelet-bound IgG was not determined. There was a relatively wide range in the level of PAIgG in the control rabbits (81 ± 168 molecules of SpA per platelet [mean ± 2 SD, $n = 39$; range of 10 to 361]). The range is similar to the range of PAIgG in healthy humans using a similar assay. The large range may reflect the difficulty in precisely measuring very low levels of PAIgG plus the large sample size ($n = 39$).

The infusion of the antiplatelet antiserum into the rabbits resulted in a significant fall in platelet count ($P < 0.05$) that was inversely correlated with the rise in the level of PAIgG. The level of PAIgG increased from an average of 81 molecules of IgG per platelet (normal rabbits) to a mean of 2,400 molecules of SpA per platelet (Fig 3A). The level of PAIgG was significantly correlated with the amount of antiserum injected ($r = 0.94$) and more importantly, with the severity of the thrombocytopenia ($r = 0.86$) as shown in Fig 4A. Sham-treated animals and animals administered nonimmunized guinea pig serum did not have a change in the platelet count or level of PAIgG.

The level of PAIgG was also measured in the animals with nonimmune destructive and nonimmune aregenerative thrombocytopenia. Nonimmune destructive thrombocytopenia was produced by the infusion of adenosine diphosphate (ADP) into rabbits. Other investigators have shown that ADP infusions result in a dramatic fall in the platelet count, presumably due to platelet sequestration within the lungs and microcirculation.[15] When the rabbits were administered ADP, the platelet count immediately fell to similar levels caused by the antiplatelet antibody. Yet, when the level of PAIgG was measured on the platelets from these rabbits, it remained within normal limits (Fig 3A), and there was no correlation between the severity of the thrombocytopenia and the level of PAIgG (Fig 4B). To exclude the possibility that nonimmune thrombocytopenia of a longer duration might product a rise in PAIgG, ADP was infused daily into rabbits, and the platelet-bound IgG was measured on day 4. The level of PAIgG remained within normal limits.

Aregenerative thrombocytopenia was produced by irradiation of the rabbits. This treatment results in destruction of stem cells and megakaryocytes, and the platelet count fell to an average of 50% of the pretreatment platelet count at five to eight days following irradiation. There was considerable variation in the life span of platelets in these animals ranging from normal (63 hours) to moderately shortened (11 hours) with the overall mean being 30 hours (Table 1). The reason for the shortened platelet life span in irradiated animals is uncertain but could be due to "fixed" platelet requirements, as has been postulated by one group of investigators.[16] Alternatively, infection could have caused some degree of platelet destruction; however, this hypothesis is unlikely, as the animals appeared healthy and blood cultures in four animals were negative for pathogens. Regardless of the precise cause for the slightly shortened platelet life span in these animals, the severity of the thrombocytopenia was equal to or more severe than the thrombocytopenia in the animals given the antiplatelet serum, yet in no irradiated animal did the level of PAIgG rise.

In none of our studies were we able to demonstrate any correlation between the severity of the thrombocytopenia and the level of PAIgG except in those animals whose thrombocytopenia was caused by immune mechanisms (Fig 4). These studies indicate that thrombocytopenia by itself is no associated with elevation in the level of PAIgG. However, it should be noted that we were only able to produce moderate thrombocytopenia in the animals, and it is possible that if the animals became extremely thrombocytopenic, slight elevations in the level of PAIgG might have been observed. Against this hypothesis is the demonstration that the fall in the platelet count in the nonimmune thrombocytopenic animals was equal to or greater than that achieved with the immune thrombocytopenic animals. Yet in contrast to the markedly elevated levels of PAIgG in the immune thrombocytopenic animals, there was absolutely no change in the level of PAIgG in the nonimmune thrombocytopenic animals. Looking for further evidence against the possibility that more severe thrombocytopenia might have "unmasked" a slight elevation in PAIgG, we carefully examined the level of PAIgG in those animals with the most severe nonimmune thrombocytopenia (Fig 3). In none of these animals was there even a trend toward increased levels of PAIgG.

In summary, these studies indicate that elevated levels of PAIgG are specific findings of immune thrombocytopenia and are not observed in animals with well-characterized nonimmune thrombocytopenia. Taken in conjunction with previous studies in humans, the current investigations support our hypothesis that immune mechanisms contribute to more thrombocytopenic disorders in humans than was once thought likely.

Immature Dense Granules in Platelets From Mice With Platelet Storage Pool Disease

By Madonna Reddington, Edward K. Novak, Edward Hurley, Chitra Medda, Michael P. McGarry, and Richard T. Swank

Mepacrine uptake into platelets and bone marrow megakaryocytes was analyzed to further characterize the dense granule defects in a group of seven mouse pigment mutants that have characteristics of platelet storage pool disease (SPD). In contrast to our previous studies using electron microscopy, this method revealed that all mutants had normal numbers of dense granules. However, total mepacrine uptake in all mutant platelets was significantly diminished to less than 50% of normal uptake. Also, the flashing phenomenon observed when normal dense granules are irradiated with ultraviolet light was either greatly diminished or absent when platelets of individual mutants were similarly irradiated. Therefore the principal defect in the mutant platelets is an inability to accumulate dense granule contents rather than an absence of the granules. Mepacrine uptake into megakaryocytes was indistinguishable in normal and mutant mice. This indicates the mutant dense granule defects appear either very late in megakaryocyte development or early in platelet formation in correlation with development of the mature dense granule. By standard transmission electron microscopy we have not been able to detect gross structural or subcellular abnormalities in either platelets or megakaryocytes of mutant mice. It appears all seven mutants produce immature or functionally abnormal dense granules.

SEVEN (beige, pearl, pallid, maroon, ruby-eye, light ear, and pale ear) separate recessive mutations of the mouse, which cause diluted pigmentation, have been shown to have associated increased bleeding times together with platelet storage pool disease (SPD).[1] The beige mouse[2] is an animal model for human Chédiak-Higashi syndrome (CHS),[3] and the remaining mutants are candidate animal models for other human platelet storage pool diseases such as Hermansky-Pudlak syndrome (HPS).[4,5] The symptoms of human platelet storage pool deficiency have been subclassified into four groups.[6] This suggests human SPD, like mouse SPD, may be caused by different genetic loci.[6]

These seven mouse pigment mutants have defects in structure and/or function of at least three subcellular organelles. First, melanosomal abnormalities in several cases are responsible for their diluted pigmentation.[7] Second, all have abnormal secretion of lysosomal enzymes from kidney proximal tubule cells.[8,9] Also, when platelets are stimulated with thrombin, abnormal lysosomal enzyme secretion is observed in beige, pearl, pallid, light ear, and pale ear.[1] Similarly, when macrophages of pale ear mice are treated with amines, lysosomal enzyme secretion is reduced.[10] A well-documented presence of giant lysosomes occurs in many tissues of the beige mouse[11] as well as in patients with CHS syndrome.[3] Ceroid-like deposits observed in kidneys of mouse models of HPS[12] have recently been described in an autopsy of a HPS patient.[13] The third defective organelle in all seven mouse pigment mutants is the platelet-dense granule. Platelets from all seven mutants have abnormally low dense granule contents such as adenine nucleotides and serotonin.[1,14] Also, by electron microscopic analyses of whole-mounted platelets, very few dense granules are visible in any mutant platelets, and most platelets have no dense granules.[1,14] Thus these mouse pigment mutants emphasize the interrelatedness of different subcellular organelles and represent a rich source of separate genes that control the biogenesis, structure, and/or processing of these organelles.

By reciprocal bone marrow transplantation,[15,16] we have shown that in all seven mouse models of platelet storage pool deficiency the bleeding defect is likely due to an intrinsic defect expressed in marrow-derived platelet progenitor cells. To determine the stage in platelet or megakaryocyte development in which the dense granule defect first appears, the fluorescent dense granule marker, mepacrine, was used. This basic compound provides a useful method of monitoring dense granules of platelets and megakaryocytes, since it is rapidly and specifically concentrated in dense granules.[17,18] We report our analyses of dense granules of platelets and megakaryocytes of normal and seven separate SPD mouse mutants using mepacrine labeling. The results obtained using animal models for SPD are compared to those described in patients with CHS and HPS.

METHODS

Animals. Normal C57BL/6J and congenic or coisogenic homozygous mutants—beige (*bg/bg*), pearl (*pe/pe*), pallid (*pa/pa*), light ear (*le/le*), pale ear (*ep/ep*), maroon ($ru\text{-}2^{mr}/ru\text{-}2^{mr}$), and ruby (*ru/ru*)—were either obtained from the Jackson Laboratory, Bar Harbor, ME, or were bred in our animal facilities. Animals approximately 2 to 4 months of age and of both sexes were used. The properties of these pigment mutants, which exhibit symptoms of platelet storage pool diseases, are reviewed by Novak et al,[1] and their history is reviewed by McGarry et al.[16]

Isolation of platelets and megakaryocytes. Animals were killed by anoxia with CO_2. Blood was collected by heart puncture into a 22-gauge needle attached to a 1-mL syringe containing 0.1 mL 3.8% sodium citrate.[19] Platelet-rich plasma was isolated by centrifugation ten minutes at 150 g.[20]

Megakaryocytes were flushed from each femur with 0.75 mL "mega" medium containing 1 mmol/L adenosine, 2 mmol/L theophylline, 18.7 mmol/L Hepes buffer, 100 mmol/L glycine, 5 mmol/L EDTA, and 5% fetal calf serum in calcium and magne-

sium-free Hanks' balanced salt solution, pH 7.0, containing 40 U/mL of DNase.[21] The bone marrow cell suspension (3 to 5 × 10^8 cells/mL) was filtered through a wire 200 mesh filter, then partially purified first by Percoll gradients followed by Ficoll density gradient (2% to 5% Ficoll) centrifugations according to Rabellino et al.[22] In later procedures the Percoll gradient fractionation was eliminated, since the percent purification was unchanged and yield was improved. Filtered bone marrow cell suspension (1.5 mL) was layered onto a 12.0 mL 2% to 5% Ficoll gradient and spun at 100 g for ten minutes. The pellet was resuspended in 1.0 mL mega medium, layered onto a second 6-mL 2% to 5% Ficoll gradient, and centrifuged at 100 g for ten minutes. The pellet was resuspended in 1.0 mL mega medium and used immediately. Samples were stained for acetylcholinesterase (specific for rodent megakaryocytes and precursors,[23] to monitor the purification. Typically, partially purified preparations contained 10% megakaryocytes. In control experiments it was found that both small and large bone marrow cells accumulated mepacrine in granules. To selectively analyze megakaryocytes for mepacrine uptake, only cells larger than 20 μm in diameter were monitored. Analysis of partially purified megakaryocyte preparations revealed that 60% of acetylcholinesterase-positive cells had diameters larger than 20 μm, whereas 90% of acetylcholinesterase-negative cells had diameters less than 20 μm. Thus this procedure ensured that we were preferentially monitoring uptake into megakaryocytes, although it did not allow measurements on smaller (<20 μm) megakaryocytes.

Mepacrine uptake. Platelet-rich plasma containing 5 × 10^{-5} mol/L mepacrine was incubated for 30 minutes at 37°C. Platelets were harvested by centrifugation at 1,000 g for ten minutes, washed twice with Tyrode's calcium-free solution,[1] and resuspended in the above Tyrode's solution at a 3 to 5 × 10^8 cells/mL. A drop of platelet suspension was placed on a glass slide with coverslip. After five minutes cells were analyzed in a Leitz MPV-2 fluorescent microscope with photomultiplier attachment. A mercury lamp (Osram model HBO, 200W/L2) with excitation filter at 450 to 490 nm and emission filter passing wavelengths above 510 nm was used. Platelets and megakaryocytes were analyzed under oil at 1,000 × magnification. Extraneous light was minimized by centering cells in the middle of a constricted circle formed by an iris diaphragm. The number of granules in individual cells was first counted. After a few seconds the granules began flashing. Both individual granules and granule flashes were recorded visually. Light photomicrographs of platelets were obtained in separate experiments with Kodak Tri-X Pan 400 film using the same microscope by exposing the cells to ultraviolet light for only five seconds to avoid the flashing phenomenon that occurs upon prolonged exposure to ultraviolet light.

Intensity of fluorescence (millivolts) was determined in separate platelets with a MPV-2 Leitz-Wetzlar photomultiplier together with recorder. To avoid discharge of granule contents by prolonged irradiation with UV light, the illuminated field was changed after examination of each cell. Standard curves with known concentrations of mepacrine in solution over the entire range of intensities recorded in platelets and megakaryocytes verified that the response was linear.

Electron microscopy. Platelets and partially purified megakaryocytes were prepared for electron microscopy according to White.[24,25] Specimens for electron microscopy were initially fixed in 0.1% glutaraldehyde in White's buffer and washed in buffer before fixation in 3% glutaraldehyde in Sorensen's phosphate pH 7.3 or White's buffer. They were rinsed in phosphate buffer, postfixed in 1% Osmium tetroxide, and embedded in Epon-Araldite. Sections were cut on an LKB III ultramicrotome, stained with uranyl acetate and lead citrate, and examined with a Siemens 101 electron microscope. Samples from two normal and two of each of the mutant mice were analyzed.

RESULTS

Mepacrine accumulation in platelets. Mepacrine was observed (Fig 1) to accumulate in discrete granules in normal and mutant platelets. Platelet cytoplasm contained only diffuse weak fluorescence. Photographs of platelets of three mutants—beige, pallid, and pale ear—are presented, but qualitatively similar results were obtained in all seven mutants of this study. Granules in normal platelets were more intense (see below) than in mutants, indicating an increased capacity to accumulate mepacrine.

When the number of platelet granules that accumulate mepacrine was enumerated (Table 1), there was in fact no significant difference between normal platelets and platelets from each of the seven mutants. All had five to six dense granules on average per platelet. One possible explanation of this result was that lysosomes were being counted as dense granules in mutant platelets. Mepacrine is an amine that is classified as a weak base. Weak bases are known to accumulate in lysosomes in several cell types.[26,27] To test whether mepacrine was taken up into lysosomes in addition to dense granules, we took advantage of the fact that both normal and beige platelets take up and secrete serotonin from dense granules after thrombin stimulation, while only beige platelets are selectively inhibited in lysosomal enzyme secretion.[1] Thus if mepacrine were taken up primarily into dense granules, mepacrine-containing granules would be equally and efficiently secreted on thrombin stimulation from both normal and beige platelets. If lysosomes were involved, normal platelets would secrete more mepacrine-containing granules than beige platelets. When thrombin-treated platelets were examined by light microscopy, both normal and beige platelets secreted all mepacrine-containing granules, indicating that in mouse platelets mepacrine accumulates primarily in dense granules. Skaer et al[18] have likewise presented evidence that mepacrine stains the dense bodies of platelets, not platelet lysosomes.

When an individual platelet was illuminated with ultraviolet (UV) light, discrete mepacrine-containing granules were observed. However, within a few seconds the granules began to flash and subsequently to fade. The flashing phenomenon, while incompletely understood, is thought to be a qualitative measure of the physical/chemical environment within the dense granule.[17] Illumination with UV light probably causes release of mepacrine into cytosol where it is less quenched, thus resulting in "flashing." It is apparent (Table 1) that there are marked differences in the flashes/platelet in normal and mutant mice. In normal mice the flashes per platelet are identical to the number of dense granules per platelet, indicating each dense granule flashes. In contrast, platelets of beige, pearl, and pallid mice exhibit little or no flashing (3% to 6% normal values). Higher rates of flashing were apparent in the light ear and pale ear mutants (43% and 37%, respectively, of normal) and the ruby-eye and maroon mutants (25% and 17% of normal). Thus in each of the mutants the number of flashes/granule is reduced, although the number of mepacrine-containing granules is normal.

Mepacrine accumulation during a 30-minute incubation was measured as the relative fluorescence intensity/platelet.

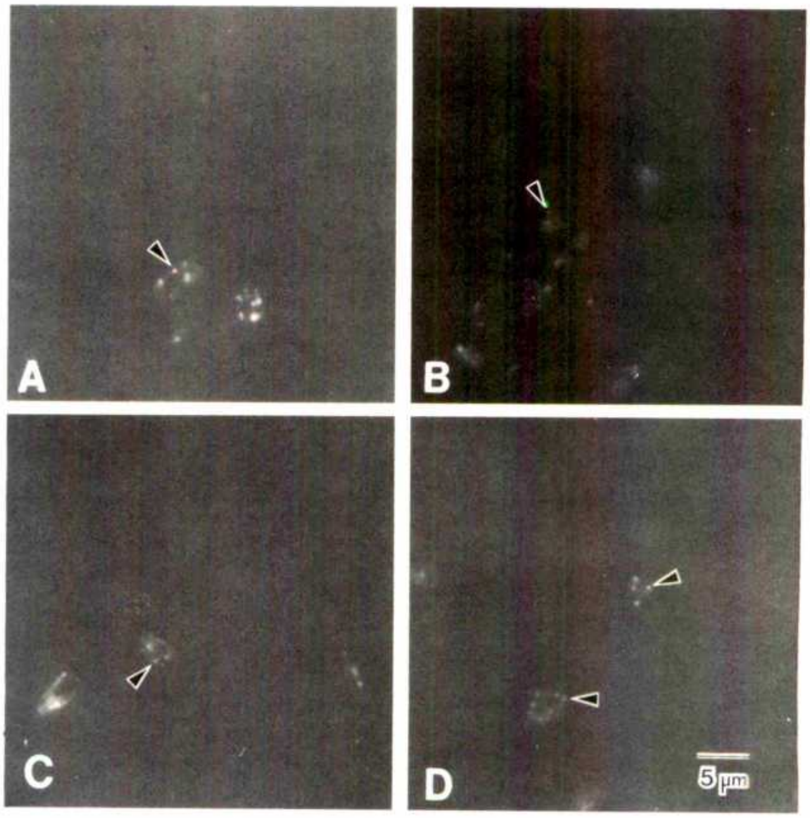

Fig 1. Visualization of dense granules in mepacrine-labeled platelets. Platelets from normal and mutant mice were treated with mepacrine, washed, and observed in a fluorescent microscope and photographed. In both normal and mutant platelets, mepacrine was localized in discrete granules (arrows). (A), normal; (B), beige; (C), pallid; (D), pale ear.

Platelets from all mutants accumulated less mepacrine than normal platelets. Of interest is the fact that the beige, pearl, and pallid mutants that were most abnormal in regard to the flashing phenomenon also accumulated the least mepacrine, only 19%, 16%, and 17%, respectively, of normal platelets. In the remaining four mutants, mepacrine accumulation was between 27% and 50% of normal accumulation.

Mepacrine uptake into megakaryocytes. Mepacrine uptake into partially purified large (>20 µm) megakaryocytes of bone marrow of normal and mutant mice was quantitated by fluorescence (Table 2). No significant difference in intensity was noted between normal and mutant cells. The variation in intensity within normal or mutant megakaryocytes was large. Plots of intensity *v* size (not shown) showed that this variation in mepacrine uptake was not correlated with cell diameter. It was also noted that the intensity of all megakaryocytes per unit cell volume was much less than that of platelets (compare Tables 1 and 2) given the fact that megakaryocytes may give rise to about 4,000 to 8,000 platelets.[28]

Although individual mepacrine-containing organelles were clearly visible in normal and mutant megakaryocytes, we did not attempt to count them because it was not possible to visualize all organelles in one focal plane in the relatively thick megakaryocytes. A significant finding was that flashing of mepacrine-labeled granules was observed in a small number (~1%) of normal megakaryocytes but was never observed in megakaryocytes from any of the seven mutants.

Electron microscopic analysis of normal and mutant platelets and megakaryocytes. Standard transmission electron microscopy of osmium-fixed thin sections revealed no gross structural abnormalities in mutant platelets (Figs 2

Table 1. Mepacrine Uptake in Platelet Granules

	Granules/Platelet	Flashes/Platelet	Flashes/Granule	Relative Intensity/Platelet (mV)
Normal C57BL/6J	6.2 ± 0.54	6.0 ± .69	0.99	73 ± 7.2 (100)

Maroon	6360 ± 880 (40)

Quantitative fluorescence values represent the mean ± SEM of the indicated number (in parenthesis) of megakaryocytes.

and 3). Although for comparison we have presented only pictures of normal and pallid platelets, all seven mutants and normal cells gave indistinguishable profiles for each cell type. All mutant cells had normal size and shape. Mutant platelets displayed the prominent circumferential ring of microtubules and appeared to have a normal intracellular complement of granules, mitochondria, and glycogen particles, and these organelles displayed a normal morphology. We did not attempt to analyze dense granules by this method. Platelet-dense granules are rarely seen in thin sections and are difficult to distinguish unequivocally from other platelet granules in these sections. Similarly, electron microscopic analysis (not shown) of megakaryocytes from normal and mutant mice revealed no gross structural abnormalities.

DISCUSSION

A major conclusion of this study is that all seven mouse pigment mutants, previously characterized as animal models of platelet storage pool disease and as having very few dense granules by electron microscopic analysis of unfixed, whole-mounted platelets[1] actually contain normal numbers of immature dense granules. The mutant platelet granules, however, are qualitatively abnormal. They accumulate much less mepacrine than normal granules and exhibit fewer flashes. In both of these properties, the mutants are divisible into two major groups. The beige, pearl, and pallid platelets have a near absence of flashes and less than 20% normal mepacrine accumulation, while light ear, pale ear, ruby-eye, and maroon platelets flash at 17% to 44% the normal frequency and accumulate 27% to 50% the normal mepacrine concentrations. In previous experiments[1] it was likewise found that the mutants were separable into the same two groups when concentrations of platelet-dense granule contents such at ATP and serotonin were examined. A likely explanation for the correlation between lowered mepacrine accumulation and decreased platelet-dense granule contents is that mepacrine has been shown to bind with high affinity to dense granule components such as ATP.[27] The lowered accumulation of mepacrine in mutant platelets is in agreement with the previously determined[1,14] lowered rate of accumulation of another dense granule component, serotonin, in the pearl, pallid, light ear, and pale ear mutants. Taken together the data suggest platelets from all seven mutants have normal numbers of immature platelet-dense granules that are unable to retain normal quantities of dense granule components.

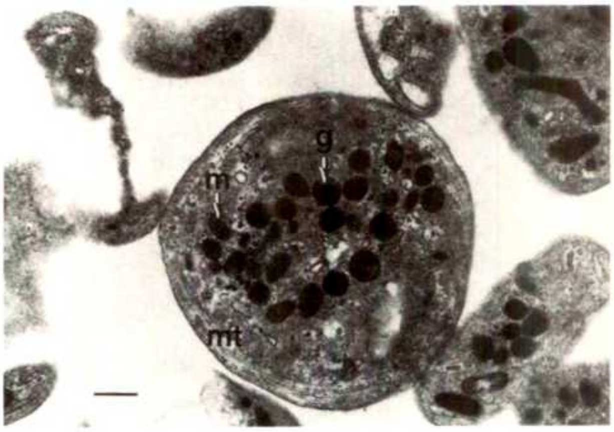

Fig 3. Analysis of platelets from pallid mice by transmission electron microscopy. Abbreviations: m, mitochondrion; mt, microtubule; g, granule. Measuring bar = 0.5 μm.

The results of these experiments can be compared to studies on various human and animal platelet storage pool diseases. In humans the two most studied forms of storage pool disease are Chédiak-Higashi (CHS) syndrome[3] and Hermansky-Pudlak syndrome (HPS)[4,5]

Several studies[11,29-31] of CHS platelets have demonstrated reduced levels of dense granule contents such as serotonin, ADP, and ATP. Most[29,32] but not all[11] morphological analyses of human CHS platelets have revealed decreased numbers of dense bodies.

In platelets from animal models of CHS storage pool disease,[1,14,19,29,33] symptoms similar to that of human CHS occur. Morphological studies by transmission electron microscopy using White's method[34] and the uranaffin fixation method[35] revealed a marked reduction of dense granules per platelet in cattle,[34] mink,[34] cat,[34] and beige mouse[35] models of CHS. However, when mepacrine labeling was used, only a small (35%) reduction of dense granules was observed in the beige mouse model.[36] In addition, similar to our results, the relative intensity of mepacrine accumulation was one-half normal, and flashing of beige platelet granules was virtually absent.[36]

Several groups have studied platelet dense granules in HPS. By morphological studies using White's method[37] and the uranaffin method,[38] dense granule numbers were greatly reduced in platelets from HPS. By mepacrine labeling using platelets from the same patients as the uranaffin method,[38] 50% to 70% of normal platelet-dense granules were found, and fluorescence intensity was 15% to 42% of normal. Flashing was measured in one patient and found to be 10% of normal levels.[38] Mepacrine studies with platelets from the fawn-hooded rat, an animal model for HPS, revealed 86% the normal dense granule number, 81% normal intensity, and 23% normal flashing. These results are similar to those obtained for the pale ear, light ear, ruby-eye, and maroon mutants.

We believe it is likely the studies[29,34,35,37,38] reporting large decreases in numbers of platelet-dense granules in CHS and HPS reflect limitations of the methods used. Two laboratories[34,37] used White's method[24,25] to analyze thin sections, others[35,38] the uranaffin method,[35] and still another[29] the whole-mount electron microscopic method.[39] These techniques depend upon having normal or near normal concentrations of dense-granule contents for identification in the electron microscope. This is true for the whole-mount method, which uses no fixatives and relies upon the natural density of the granule, and for the uranaffin method, which depends upon reaction with ATP in the granule. In White's method external calcium is included in the fixation medium to enhance dense granule contrast, but it is uncertain if this procedure adequately labels all dense granules in SPD patients. It is commonly found that other externally added components, such as serotonin and mepacrine, accumulate in dense granules of SPD patients to a much lower degree than in dense granules of normal patients. On the other hand, the mepacrine-labeling method utilized to study SPD platelets in this study and others[36,38,40,41] is a sensitive fluorescent method that is easily capable of revealing dense granules, even if only 15% to 20% the normal concentration is taken up into dense granules. We have analyzed the same normal and mutant mouse platelets by the mepacrine (this report) and whole-mount method.[1] It was found that the latter method revealed greatly reduced numbers of dense granules, while the mepacrine technique indicated normal dense granule number. Similarly, Richards et al[35] and Lorez and Da Prada[36] analyzed platelets of beige mice by the mepacrine and uranaffin methods and found no dense granules by the latter method but near normal numbers by the former. Rendu et al[32] analyzed normal and CHS platelets by the mepacrine technique and by White's method. While both methods revealed decreased contents of dense granules in CHS patients, the decrease was much larger with White's method. Thus it appears likely that the whole-mount, uranaffin, and White's methods are well suited for revealing "full" granules, while the mepacrine-labeling method detects both "full" and "empty" granules. We believe, therefore, that taken together, the available data suggest that while there is a partial reduction of platelet-dense granules in certain cases,[32,41] the platelet-dense granule defect in SPD is due to major qualitative abnormalities in dense granules that impair their ability to accumulate normal contents rather than to an absence of dense granules per se.

Total mepacrine uptake in our studies into megakaryocytes, in contrast to platelets, was relatively low and also was not significantly different in normal and mutant mice. Thus the mutant dense-granule defects (ie, absence of dense granule contents) appear either very late in megakaryocyte development or early in platelet formation. The finding that a few (~1%) normal megakaryocytes flashed while no flashing was detectable in any mutant megakaryocytes suggests that only a small population of megakaryocytes, possibly a very late stage in maturation, contains mature dense granules. Since flashing was never seen in the mutant cells, the mutant defects likely are already present in megakaryocytes. The absence of flashing of dense granules of mutants illustrates that mutant dense granules express their immature phenotype when formed.

The low mepacrine accumulation in megakaryocytes is consistent with what is known of the timing of the accumulation of dense granule contents in normal platelets. For example, Mishory and Danon[42] found that newly formed platelets entering the bloodstream have practically no osmophilic organelles and that the number and size of these organelles increases with the age of the platelets.

The fact that mepacrine uptake is equal in normal and mutant megakaryocytes is consistent with the idea that the dense granule defect in all mutants is not in production of dense granules, since immature dense granules are present in mutant megakaryocytes. Rather, the defect seems to reside in the ability of dense granules to accumulate normal contents. Previous experiments utilizing bone marrow transplantation have shown that factors extrinsic to bone marrow precursor cells are not defective.[15,16] Also, initial rates of accumulation of one dense granule component, serotonin, are normal,[1,14] suggesting a normal transport mechanism. The defects in mutant platelets, therefore, are more likely to lie in mechanisms for retention of dense-granule components.

It is possible that some other substance(s) is present in mutant dense granules that prevents accumulation of dense-granule components and inhibits flashing. This is unlikely, at least in regard to primary gene products, since it is expected that a recessive mutation would result in a deficiency, rather than an increase, in the gene product. It remains possible that accumulation of such hypothetical substances could occur in mutant granules as a secondary effect of the mutations.

One uncertainty in interpretation of our megakaryocyte data is that, in comparison to platelets, there is less independent evidence that mepacrine uptake is principally into dense granules. The fact, however, that megakaryocytes incorporate labeled serotonin[43] is evidence that they are capable of concentrating normal dense-granule components. Also, Hourdille' et al[44] considered their finding of lowered mepacrine accumulation in megakaryocytes of a patient with a dense-granule defect as evidence that the mepacrine is incorporated mainly into dense granules.

Relatively few studies have been performed on dense granules of megakaryocytes of human storage pool disease. Hourdille' et al[44] found, in contrast to our results with mutant mice, that 74% of megakaryocytes of a patient with HPS showed no labeling with mepacrine and concluded, therefore, that the platelet anomaly is secondary to a megakaryocyte anomaly. Richards and Da Prada[35] found no positive uranaffin reaction in megakaryocytes of HPS patients or beige mice or fawn-hooded rats. However, this same method of detection also revealed[34] no positive reaction in platelets of the above mutant animals while we and Lorez et al[38] have readily detected dense granules in platelets of these mutants using the mepacrine-labeling technique. Therefore, as previously discussed, the mepacrine method may be a more sensitive method of detecting the relatively immature dense granules of megakaryocytes. Further studies on megakaryocytes of SPD patients are needed for an adequate comparison to our results using the various mouse mutants.

These results show that the normal accumulation of dense granule contents is under multigenic control with at least seven genes involved. The molecular bases for the organelle defects in the mouse mutants are still unknown. A speculative explanation of our results is that the mutants have defects in the membrane of dense granules. Probably such defects are also present in lysosomes and melanosomes,[8,9] emphasizing the relatedness of the three organelles. Our current focus is on identifying the primary gene products involved in the mouse models of SPD.

The Presence of Clonogenic Cells in High-Grade Malignant Lymphoma: A Prognostic Factor

By Mary E. Tweeddale, Bing Lim, Nazir Jamal, Jean Robinson, John Zalcberg, Gina Lockwood,
Mark D. Minden, and Hans A. Messner

A culture system has been developed that promotes growth of clonogenic lymphoma cells of some patients with intermediate and high-grade malignant lymphoma. The formation of colonies in bone marrow, lymph nodes, and peripheral blood samples is best supported by human plasma. Colony formation of some patients was dependent upon growth factors, which in this study were added in the form of medium conditioned by phytohemagglutinin (PHA)-stimulated leukocytes (PHA-LCM). Some gave rise to lymphoma colonies without PHA-LCM but improved their frequency with PHA-LCM; others were completely independent of PHA-LCM. Colonies grown in primary cultures were routinely recloned and propagated as Epstein-Barr virus (EBV)-negative cell lines with stable B cell phenotype. The cell lines showed the same immunoglobulin rearrangement pattern as that observed in the primary lymphoma sample. In addition, a significant clinical correlation was observed between culture data and clinical outcome. Survival of patients who formed lymphoma colonies at any time during their clinical course was significantly shorter than survival of patients who did not give rise to colonies ($P = 0.0009$). The same observation was made when the survival assessment was performed for the subset of patients studied at diagnosis ($P = 0.0014$).

THE MALIGNANT non-Hodgkin's lymphomas represent a diverse group of neoplasms with heterogeneous histopathologic[1,2] and clinical presentations.[3,4] A similar degree of variation is apparent when cellular properties are studied. Analysis of cell surface antigens with monoclonal antibodies (MoAbs) indicates that lymphoma cells of individual patients may reflect different stages of normal B cell or T cell differentiation.[5-7] Cell culture conditions are available to grow normal and abnormal B cells; a number of investigators have contributed to the evaluation of normal and abnormal B cell proliferation in cell culture.[8-13] Although the cell culture systems vary in detail, they all have in common the requirement for either feeder cells, cell-derived stimulating molecules, and/or mitogens such as *Staphylococcus aureus* protein A (SPA) or anti-immunoglobulin antibodies. These studies indicate that the proliferation and maturation of normal B cells may require a series of signals that are mediated by molecules[14-22] defined as B cell activator, B cell growth factor, and B cell maturation factor. It is not known whether clonogenic populations of B cell neoplasms are subject to similar controls or whether they proliferate autonomously. The exact requirements for growth are unknown. Smith et al[12] found that cells of some B cell malignancies could grow in the presence of fetal calf serum (FCS) and medium, while we observed that the growth of myeloma colonies required human plasma as well as PHA-LCM.[23] We have used the same culture system to analyze bone marrow, peripheral blood, and lymph node samples of patients with lymphoma to identify whether or not a clonogenic tumor stem cell population can be detected and propagated for further studies. In addition we examined the prognostic significance of colony growth.

MATERIALS AND METHODS

Patient Material

The patient material was contributed by collaborating physicians located at the Princess Margaret Hospital, the Wellesley Hospital, and the Sunnybrook Medical Centre, University of Toronto. As part of their diagnostic workup, bone marrow, peripheral blood, and lymph node specimens were obtained from consenting, unselected patients presenting to the above institutions with the provisional diagnosis of malignant lymphoma. In addition, samples became available from patients with malignant lymphoma in relapse. The histologic diagnosis and clinical status of the patients was unknown to the investigators until the growth pattern in culture was unequivocally determined by following cultures for at least 2 months.

Preparation of the Samples

Bone marrow and peripheral blood samples were aspirated into heparinized syringes and centrifuged in 60% Percoll to obtain a mononuclear cell suspension of density less than 1.077 g/mL. Surgically obtained lymph node sections were cut with scissors and passed through a fine wire mesh to prepare a single cell suspension.

Cell Culture Studies in Semisolid Medium

Freshly prepared cell suspensions were plated in methylcellulose as previously described.[23-25] Briefly, cells were cultured in Iscove's modified Dulbecco's minimum essential medium (IDMEM; Gibco, Grand Island, NY), 30% normal human plasma prepared under platelet-poor conditions,[24] 5×10^{-5} mol/L 2 mercaptoethanol (2ME), (Sigma, St. Louis), and 0.9% methylcellulose (Dow Chemical Co, Midland, MI). Each sample was grown with and without 10% of PHA-LCM (PHA,HA15; Wellcome Diagnostics, Dartford, England).[26] Cells were plated in duplicates, bone marrow cells at 2×10^5/mL, peripheral blood cells at 4×10^5/mL, and lymph node cells at 5 to 10×10^5/mL in 35-mm Petri dishes (LUX, Lab-Tek Division, Miles Laboratories, Naperville, IL). The cultures were incubated at 37°C in a humidified atmosphere supplemented with 5% CO_2. The plates were frequently inspected for the emergence of colonies and scored on days 10 to 14. One of the plates of each experimental group was then supplemented with an additional 1-mL

layer of the above described culture medium to allow long-term observation of the cultures at least until day 30.

The content of the second primary culture plate of each group was resuspended in IDMEM,[23] replated under identical culture conditions, and observed for 6 to 8 weeks. This recloning procedure was performed for primary cultures of all patients independent of whether or not lymphoma colonies were identified.

Studies in Liquid Suspension Culture

Primary samples that contained sufficient cells were also used to initiate liquid suspension cultures in IDMEM, 20% normal human plasma, 5×10^{-5} mol/L 2ME, and 10% PHA-LCM. This medium was completely exchanged at weekly intervals. Lymphoma colonies propagated in semisolid medium were also transferred into liquid suspension cultures and maintained as cell lines under the above described conditions.

Phenotypic Characterization of Lymphoma Cells Propagated in Long-term Cultures

Cells maintained in semisolid or liquid long-term cultures were carefully washed in IDMEM and examined on multiple occasions with a panel of MoAbs directed against B cell specific surface or cytoplasmic antigens. B1, B2, B4, and PCA1 were a generous gift of Dr Lee Nadler (Dana Farber Institute, Boston). Antibodies against the μ, δ, γ, κ, and λ chains were obtained from Tago Inc, Burlingame, CA. The panel also included MoAbs against the common ALL antigen (CALLA, J5 Coulter Immunology, Hialeah, FL), Il-2 receptor (TAC, Dr L. Nadler), the T cell subsets T3, T4, T6, and T8 (Ortho Diagnostic Systems, Don Mills, Ontario), and determinants associated with myeloid cells. T101 was kindly provided by Dr Ivor Royston (San Diego, CA). Staining was performed according to the technique described by Smith et al[27] and analyzed by immunofluorescence microscopy.

Preparation and Analysis of DNA

Cells from lymph nodes were washed twice in phosphate-buffered saline and resuspended in 10 mmol/L Tris pH 7.5, 100 mmol/L NaCl, 1 mmol/L EDTA (TNE) with 1% sodium dodecyl sulfate (SDS), and 200 μg/mL proteinase K incubated at 37°C over night and extracted sequentially with phenol: chloroform and then twice with chloroform. The DNA was precipitated with isopropanol and resuspended in 10 mmol/L Tris pH 7.5 1 mmol/L EDTA. Ten micrograms of DNA was digested with the restriction enzyme EcoR1, separated by agarose electrophoresis, and transferred to nitrocellulose.[28]

Probes

The presence of EBV was determined using a probe to BAM H1k region of EBV provided by Dr G. Miller, New Haven, CT.[29] The structure of the Ig heavy chain locus[30] was determined using a 3kb EcoR1, Hind III fragment containing heavy chain J region provided by Dr P. Leder, Boston. DNA fragments were labeled by nick translation with ^{32}P.[31]

Histologic Assessment

All lymph node specimens were classified according to Rappaport[1] and the working formulation.[2]

Statistical Analysis

The survival of patients who formed lymphoma colonies and patients who did not form lymphoma colonies was examined by Kaplan-Meier analysis[32] and compared by the method described by Mantel.[33] The two groups were tested for differences in clinical attributes using the chi-square[34] or Mann-Whitney u test.[34]

RESULTS

Clinical Data

Sixty-nine patients with non-Hodgkin's lymphoma with varying histologic phenotype and clinical stage were entered into the study. The available specimens included 31 lymph nodes, 33 bone marrow aspirates, six peripheral blood samples, one soft tissue tumor, and one mediastinal mass. Three patients were studied using material of more than one tissue source. Thirty-nine samples were obtained at diagnosis, 30 during relapse, 49 specimens were involved with lymphoma, 20 did not show any detectable lymphoma cells upon histologic and cytologic assessment. Table 1 presents a summary of the various samples from patients with non-Hodgkin's lymphoma. As can be seen, the development of EBV-negative lymphoma colonies was restricted to samples derived from patients with intermediate or high-grade malignant lymphoma.

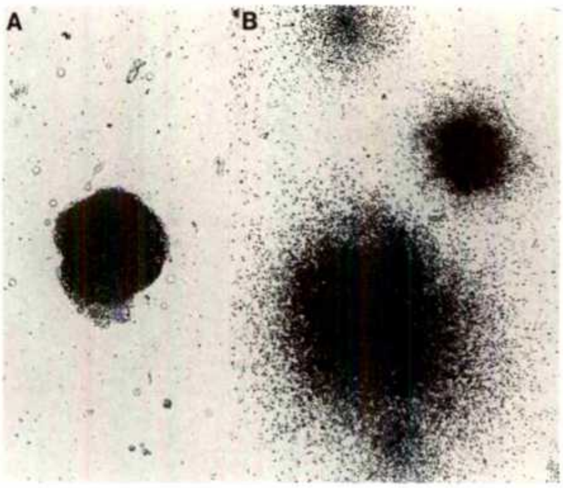

Fig 1. Variation in morphology of lymphoma colonies grown from different patients. Panel A displays a compact colony; panel B shows more loosely arranged colonies.

Lymphoma Colonies

Lymphoma colonies were grown from lymph nodes, bone marrow aspirates, and peripheral blood samples of 16 patients. The colonies were uniformly composed of round mononuclear cells and showed patient-related heterogeneity with respect to colony morphology, size, and plating efficiency. The majority of samples gave rise to compact colonies that contained between 500 and 10,000 cells (Fig 1A). Some specimens produced more loosely arranged colonies (Fig 1B). Usually colonies developed within seven to 20 days. Some cultures had to be followed for as long as 30 days to detect the formation of lymphoma colonies. The plating efficiency in primary cultures varied from 0.001 to 0.2% (Table 2). The primary plating efficiency could not be assessed for all cultures because of confluent colony growth.

While colonies grown from lymph node specimens were easily scorable as the only identifiable colony type, lymphoma colonies from bone marrow and peripheral blood samples usually developed among normal hemopoietic colonies. Compact lymphoma colonies could easily be distinguished. Identification of loosely arranged lymphoma colonies among normal hemopoietic colonies was more difficult and required confirmation by marker analysis.

Recloning Studies

Each of the primary cultures, independent of whether or not primary lymphoma colonies were observed, were resuspended in fresh medium and recultured under identical conditions. All samples that yielded primary lymphoma colonies gave rise to secondary lymphoma colonies. Growth in secondary cultures was usually associated with an increase in the plating efficiency (Table 2). Every one of the samples forming primary colonies could be propagated in semisolid medium for many generations using identical recloning procedures. None of the samples that did not form primary lymphoma colonies showed lymphoma colony growth upon replating.

Proliferation in Liquid Suspension Culture

Cells derived from these cultures could be adapted to liquid suspension culture conditions and maintained as cell lines. They are denoted as OCI-Ly 1 to 16 (Table 2). At time of last follow-up the lines had been maintained in culture for 9 to 35 months. Cultures of one patient (OCI-Ly16) were lost after 2 months due to fungal contamination. The details of the established cell lines, their plating efficiency, and

doubling time are listed in Table 2. Their current plating efficiencies vary from 0.1% to 24%, with doubling times ranging from 15 to more than 100 hours.

Marker Studies

Cells propagated in semisolid and liquid suspension cultures were examined with a panel of MoAbs directed against surface antigens of various B, T, and myeloid cells. The data are presented in Table 3. Cells of all lymphoma lines expressed some B cell markers. They were observed in heterogeneous combinations without favoring a specific phenotype. Twelve of the lines were positive for B1, two for B2, ten for B4, and four for PCA1. Seven demonstrated cytoplasmic and 13 expressed cell surface immunoglobulins. In addition, seven reacted with anti-CALLA, and four stained with anti-TAC. A subpopulation of cells of three lines showed positive results with pan-T reagents, and one additional patient displayed T101 activity.

Lymphoma growth thus was not restricted to a specific marker phenotype. Repeat assessment of the cells using the same panel of antibodies demonstrated that the phenotype of all cell lines had not changed with propagation in culture.

Two cell lines were established from the same patient with the histopathologic diagnosis of diffuse large cell lymphoma, one at diagnosis (OCI-Ly 13.1) and one at relapse (OCI-Ly 13.2). Cells of the first line reacted with the MoAb against the IL 2 receptor; cells of the second line were negative.

Marker studies were performed on one of the primary tumor tissues (OCI-Ly8). These were in agreement with the markers observed on cells of the cell line after culture.

Immunoglobulin Rearrangement

The structure of the immunoglobulin genes in the primary lymph node sample and resulting cell line were determined in six cases. The rearrangement pattern observed in the lymph node samples was in every case identical to that of the resulting cell line. A representative example is depicted in Fig 2.

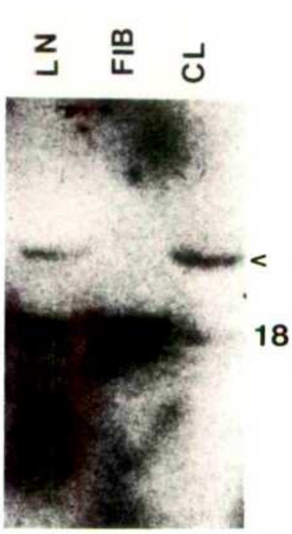

Fig 2. Immunoglobulin gene rearrangement pattern of lymph node cells (LN), skin fibroblasts (FIB), and lymphoma cells of the cell line (CL) OCI-Ly4, all derived from the same patient. The same rearrangement pattern was observed for the primary lymph node and the resulting cell line; the germ line band (18kb) is observed in DNA obtained from fibroblast cultures.

Growth Requirements

The contribution of various culture components to the growth of lymphoma colonies was assessed.

Influence of human plasma. All cell lines were examined to study the influence of human plasma in comparison to human serum derived from the same source and fetal calf serum. Plasma samples prepared under platelet-poor conditions supported linear growth even when very low numbers of cells were plated (Fig 3). In contrast, lymphoma lines grew suboptimally or not at all when platelet-poor plasma was replaced by human serum or fetal calf serum. However, cells of some lines propagated in liquid culture over long periods were adapted to fetal calf serum.

Role of PHA-LCM. The requirements of all cell lines for PHA-LCM were studied by performing dose-response curve analyses. Three growth patterns were identified, and representative examples are displayed in Fig 4. The growth of EBV-negative lymphoma colonies in nine of 14 examples were independent of added PHA-LCM. Addition of PHA-

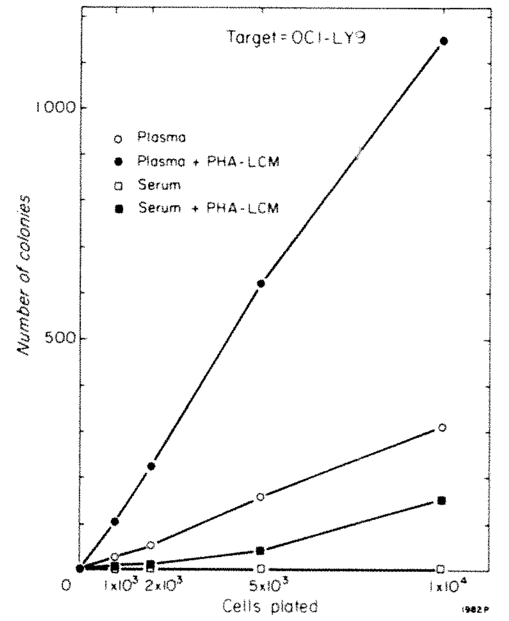

Fig 3. Influence of human plasma, serum, and PHA-LCM on the growth of lymphoma colonies.

LCM did not alter the frequency, size, or reclonability of the colonies. Four of 14 patients demonstrated formation of some colonies in the absence of PHA-LCM. Addition of PHA-LCM to these enhanced the number of colonies without influencing their size. Two cell lines (OCI-Ly 9 and OCI-Ly 13.1) gave rise to only a few small clusters of cells in the absence of PHA-LCM. Both lines formed numerous large colonies in the presence of PHA-LCM. One patient was studied on two separate occasions. Bone marrow samples became available at diagnosis (OCI-Ly 13.1) and four months later during relapse (OCI-Ly 13.2). Colony formation in the first sample was dependent upon PHA-LCM, yielding a plating efficiency of 70 colonies per 2×10^4 mononuclear cells. The second sample gave rise to 675 colonies per 2×10^4 mononuclear cells in the absence of PHA-LCM. The plating efficiency of the second sample increased to 1,240 per 2×10^4 mononuclear cells when PHA-LCM was added. The data are displayed in form of a linearity study in Fig 5.

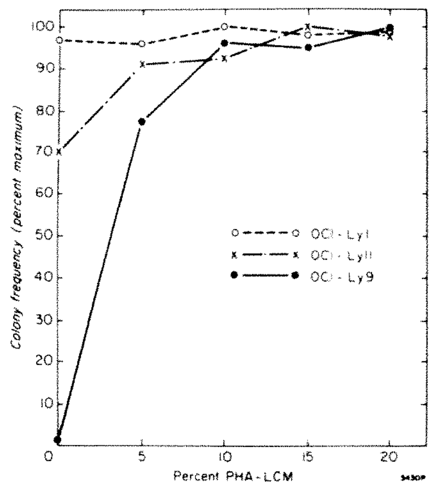

Fig 4. PHA-LCM dose-response curves representing three different patterns. Each curve was established using cells of a representative cell line.

Clinical Correlations

The examined patients represented a heterogeneous population with respect to histologic phenotype, histologic involvement of the cultured samples with lymphoma, timing of culture with respect to diagnosis, and growth pattern in culture.

The formation of EBV-negative lymphoma colonies was only observed in specimens derived from patients with lymphoma of intermediate and high-grade malignancy. The evaluation of the prognostic value of colony formation was therefore restricted to this subset of 35 patients. In addition, the patient who gave rise to the EBV-positive line OCI-Ly 15 was eliminated from the clinical analysis.

Twenty-five of the remaining 34 patients were studied at diagnosis, ten were cultured during relapse. Twenty-seven of the 34 specimens were histologically involved with lymphoma. Seven did not show signs of tumor involvement; all of the latter were bone marrow specimens. The samples of 14 patients gave rise to EBV-negative lymphoma colonies. Nine were obtained at diagnosis; five during relapse (Table 4). Specimens of 13 patients did not grow. Ten of these were collected at diagnosis; three during relapse. Both groups of patients were evenly matched for sex, histologic diagnosis, staging, and presence of B symptoms (all P values > 0.1 by chi-square analysis). The median age of nongrowers was higher than that of growers ($P = 0.009$, Mann-Whitney).

The majority of patients received BACOP combination

chemotherapy (bleomycin, adriamycin, cyclophosphamide, oncovin, and prednisolone)[35]; one was treated with PRO-MACE-MOPP (epipodophyllotoxin, cyclophosphamide, adriamycin, methotrexate, and prednisone).[36] Patients were observed for 6 to 35 months with a median of 14 months. The time of follow-up is the same for both subgroups of patients. Eight of the 13 patients who did not form lymphoma colonies are currently alive. One patient died with sepsis during inductive chemotherapy; four patients died with progressive disease.

In contrast, only one patient is surviving of the 14 who formed lymphoma colonies. Two died with septicemia, ten with progressive disease unresponsive to further therapy, and one patient died with a coexisting carcinoma of the lung. The cell line OCI-Ly 12 derived from the lone survivor is characterized by a doubling time that exceeds 100 hours and is the slowest of all lymphoma lines.

The survival of both groups was evaluated and displayed as Kaplan-Meier plots.[32] The curves were compared according to Mantel.[33] The analysis was performed for the whole group of 34 patients and for selected subgroups as listed in Table 5.

The median survival from diagnosis of all patients who formed lymphoma colonies was 7 months. In contrast, patients who did not form lymphoma colonies showed a significantly longer median survival of 25 months ($P = 0.0009$, Table 5, Fig 6).

A similar observation was made when only patients who were studied with cell cultures at diagnosis were included in the analysis. The median survival of growers was 6 months, while the median for nongrowers was not reached at 22 months. A comparison of the survival curves yielded a significant difference with a P value of 0.0014 (Table 5, Fig 6).

The median survival of growers was also significantly shorter if only the 27 patients who demonstrated histologically involvement with lymphoma of the plated specimen were analyzed (Table 5).

Nine patients were examined in relapse. Five of these grew lymphoma colonies. All five patients died within 2 months after relapse. Their median survival from diagnosis was 13 months. Two of the four patients who did not form lymphoma colonies died within 2 months, one patient survived 3 months, and one is alive 7 months after the study. The median survival from diagnosis for this subgroup was 18 months. These groups are too small to allow any meaningful statistical comparison.

DISCUSSION

A number of risk factors affecting prognosis can be identified in patients with lymphoma. These include histologic phenotypes, stage of disease, cytogenetic parameters,[37,38] expression of the transferrin receptor,[39] and response to chemotherapy.[35,36] Particularly, the latter segregates patients in the high-risk group who may have a long-term therapeutic benefit from patients who will succumb early to progressive disease. Recent encouraging results in autolo-

Comparison of the survival curves in both panels yielded a significant difference using the generalized Savage test.

gous and allogeneic bone marrow transplantation of patients with lymphomas have suggested that some patients who have relapsed with progressive disease may still be salvageable by transplantation.[40-43] This therapeutic option may be used with greater advantage earlier in the clinical course.

A culture system is described that promotes growth of lymphoma colonies in bone marrow, peripheral blood, and lymph node samples of a subgroup of patients with lymphoma belonging to a high-risk group based on histology. Growth was observed at the initial assessment or at times of re-examination for disease recurrence.

A number of observations strongly support the view that the clonogenic cells detected in the system are part of the original disease. First, whenever examined the cell lines demonstrate the same clonal immunoglobulin gene rearrangement pattern as that observed in the primary tumor. Second, the same immunoglobulins were observed on cells of the cell lines and the primary lymphoma tissue. Third, cells of the cell lines are EBV-negative and can be propagated indefinitely in liquid suspension or semisolid culture. Fourth, patients whose lymphoma cells grew in culture had a significantly poorer prognosis.

The system described here is therefore useful in identifying patients at the time of diagnosis as potential treatment failures. This group of patients may be considered earlier in their clinical course for innovative treatment approaches, such as bone marrow transplantation.

In addition to being useful as a prognostic parameter, the cell culture system may provide insight into biological aspects of malignant lymphoma. One of the areas to be explored is the heterogeneous requirement of clonogenic lymphoma cells for PHA-LCM. Clonogenic lymphoma cells of some patients are dependent upon addition of PHA-LCM to the culture. This suggests that these cells require exogenous signals for their proliferation. Some cell lines give rise to a few lymphoma colonies without PHA-LCM but show an increased plating efficiency in the presence of PHA-LCM. The third group of patients forms lymphoma colonies without PHA-LCM, and improves neither their frequency nor their size in the presence of PHA-LCM. These data may either suggest the existence of clonogenic subpopulations with differing requirements for PHA-LCM or may indicate the autocrine or paracrine production of PHA-LCM-like stimulatory substances by lymphoma cells. The availability of cell lines that have retained the various types of PHA-LCM requirement will facilitate studies to delineate the underlying mechanism. They will also provide the opportunity to compare the activity in PHA-LCM with defined purified or recombinant hemopoietic growth factors.

Observations on a single patient have provided a further lead to understand the heterogeneity in PHA-LCM requirement. This patient was initially studied at diagnosis. Colony formation of a bone marrow sample was almost completely dependent upon PHA-LCM. The patient went into a complete remission and was re-examined four months later during relapse. The growth requirement of clonogenic lymphoma cells obtained from a bone marrow specimen at that time had changed. A large number of colonies were observed without PHA-LCM. The colony frequency and size increased only slightly in its presence. The patient did not respond to further therapy and died with progressive disease shortly after the time of study. These results suggest that the requirement for PHA-LCM may change during the clinical course of an individual patient. In this isolated example a decrease in PHA-LCM requirement reflected disease progression. If verified by kinetic studies in other patients the PHA-LCM requirement may, in addition to colony growth, provide a further prognostic indicator.

ACKNOWLEDGMENT

The authors are grateful to colleagues at the Princess Margaret Hospital, the Wellesley Hospital, and the Sunnybrook Medical Centre, University of Toronto for their cooperation in providing the clinical material. Dr L. Nadler, Dr J. Royston (San Diego), Dr G. Miller (New Haven, CT) and Dr P. Leder (Boston) kindly provided some of the reagents. The authors also wish to thank Lorraine Dwyer for her help in preparing the manuscript.

The Pathogenesis of Accelerated Fibrinolysis in Liver Cirrhosis: A Critical Role for Tissue Plasminogen Activator Inhibitor

By Steven L. Hersch, Thomas Kunelis, and Robert B. Francis, Jr

The pathogenesis of accelerated fibrinolysis in liver cirrhosis was investigated by comparing the results of specific assays for tissue plasminogen activator (tpa) antigen, tpa activity, tpa inhibitor, and alpha-2 plasmin inhibitor (a2PI) in 12 patients with cirrhosis and markedly accelerated fibrinolysis (dilute whole blood clot lysis time (DWBCLT) < two hours), in nine patients with cirrhosis and moderately accelerated fibrinolysis (DWBCLT two to four hours), and in nine patients with cirrhosis and normal fibrinolysis (DWBCLT > four hours). Mean tpa antigen was markedly increased in all three groups, but no correlation was observed between overall fibrinolytic activity as measured by the DWBCLT and the level of tpa antigen. In contrast, there was a significant correlation between overall fibrinolytic activity and tpa activity and an equally significant correlation between fibrinolytic activity and decreased tpa inhibition. Mean a2PI activity was significantly lower than normal in groups 1 and 2 but was normal in group 3. The pathogenesis of accelerated fibrinolysis in liver cirrhosis thus appears to depend critically on the capacity of plasma inhibitors to inhibit increased circulating tpa antigen. Reduced a2PI also appears to play a role.

© 1987 by Grune & Stratton, Inc.

ACCELERATED fibrinolysis is a recognized complication of cirrhosis.[1-3] The liver is not only an important site of clearance of circulating plasminogen activators[4] but also synthesizes the main plasmin inhibitor, alpha-2 plasmin inhibitor (a2PI).[5] Thus a multifactorial pathogenesis of accelerated fibrinolysis in cirrhosis has been presumed, with contributions from elevated levels of circulating plasminogen activators caused by decreased clearance[6,7] and reduced inhibition of plasmin due to diminished a2PI synthesis.[8] Previously published studies of fibrinolysis in cirrhosis have not, however, investigated the interrelationship of multiple abnormalities of the fibrinolytic system, nor have they attempted to correlate these abnormalities with either overall fibrinolytic activity of blood or with clinical manifestations. Moreover, the recent discovery of one or more rapid inhibitors of tissue-type plasminogen activator (tpa) in plasma[9-11] has revealed a new complexity in the physiologic regulation of fibrinolysis. The behavior of tpa inhibitor in liver cirrhosis has yet to be investigated.

We previously reported that accelerated fibrinolysis may have significant clinical consequences for individuals with liver cirrhosis.[12] In comparing bleeding histories of 46 patients with markedly accelerated fibrinolysis (DWBCLT < two hours) to 44 patients with normal fibrinolysis (DWBCLT > four hours), we found that patients with accelerated fibrinolysis were at increased risk for major soft-tissue hemorrhage after trauma and exhibited a trend toward increased intracranial bleeding, usually fatal.[12] Other hemostatic abnormalities may have contributed to the increased bleeding in patients with accelerated fibrinolysis, however, since this group had a significantly longer mean partial thromboplastin time (PTT) and higher mean levels of fibrin/fibrinogen degradation products (fdp/FDP) than the group with normal fibrinolysis. Nevertheless, in several patients with severe bleeding, accelerated fibrinolysis was the only marked hemostatic abnormality present.

This study raised many important questions. What specific abnormalities of fibrinolysis contribute to accelerated fibrinolysis in patients with cirrhosis? Which are the most important? Why does fibrinolytic activity vary so greatly among individuals with apparently equally severe liver disease? In an attempt to answer these questions, we undertook a comprehensive evaluation of the fibrinolytic system in patients with liver cirrhosis using newly developed, highly specific assays for tpa antigen and activity, tpa inhibitor, and a2PI.

MATERIALS AND METHODS

Patient selection. The records of the Coagulation Laboratory of the Division of Hematology at Los Angeles County (LAC) University of Southern California (USC) Medical Center were reviewed to identify those patients with liver disease in whom fibrinolytic activity had been measured with the DWBCLT. The diagnosis of cirrhosis was confirmed by a review of the medical records for each patient identified. Patients were considered to have cirrhosis if they showed either biopsy evidence of cirrhosis or documented portal hypertension (presence of esophageal varices or redistribution of tracer to spleen and bone marrow on liver-spleen scanning) in the setting of parenchymal liver disease and appropriate historic background (heavy alcohol consumption or chronic hepatitis). Patients with acute hepatic necrosis secondary to viral or toxic agents were excluded. All patients meeting these criteria were included in the analysis, provided sufficient stored plasma obtained at the same time as the DWBCLT was available for performance of all the fibrinolytic assays. To determine the possible influence of transfused blood products on the results of fibrinolytic assays, the records of the LAC-USC Medical Center blood bank were reviewed, and notation was made of the quantity and type of all blood products received in the seven days preceding the date of plasma sampling. In calculating the total amount of plasma received by each patient, we assumed that one unit of fresh frozen plasma contained 225 mL of plasma, one unit of packed red cells 75 mL, and one unit of platelets 50 mL. For determination of the normal range for fibrinolytic assays, blood

was obtained from resting healthy adult donors without history of bleeding or thrombosis. The principles of the Declaration of Helsinki were followed in the care of all patients.

Preparation of plasma samples and euglobulin precipitates. All samples were obtained by atraumatic venipuncture and anticoagulated with one-tenth volume of balanced citrate. Plasma was prepared by centrifugation for ten minutes at 10,000 rpm at 4°C and stored at −20°C or −85°C until assayed. The euglobulin fraction of plasma was obtained by diluting 0.5 mL of plasma in 20 volumes of ice-cold 0.014% acetic acid (pH 5.6) prepared fresh daily from a 1.4% stock solution. After incubating for at least 30 minutes on melting ice, the precipitate was recovered by centrifugation for ten minutes at 2,500 rpm at 4°C and resuspended in 0.5 mL of 0.01 mol/L phosphate, 0.15 mol/L NaCl, pH 7.4, containing 0.1% (vol/vol) Tween 80 (PBS-Tween).

Materials. Tissue plasminogen activator (tpa) was purified from the conditioned medium of Bowes human melanoma cell cultures as previously described.[13] Human plasminogen (glu/lys mixture) and goat antihuman tpa antibody were obtained from American Diagnostica (Greenwich, CT). Cyanogen bromide-fragmented fibrinogen was prepared as previously described.[14] D-valleu-lys-pNA (S-2251) was obtained from Helena Laboratories (Beaumont, TX). Crystallized bovine serum albumin was obtained from Sigma Chemical (St. Louis). All other materials were of the highest quality obtainable.

Measurement of tpa antigen. The ELISA method of Bergsdorf et al,[15] commercially available through American Diagnostica (Greenwich, CT), was used. Briefly, 96-well flat-bottomed microtiter plates (Nunc Immunoplate I-F) were coated overnight at room temperature with goat antihuman tpa antibody, followed by washing with 0.15 mol/L NaCl containing 0.1% (vol/vol) Tween 80 (saline-Tween), and blocking of unreacted binding sites with 2% bovine serum albumin (BSA) for one to two hours at room temperature. After washing again, diluted euglobulin precipitates of test plasmas and a range of concentrations (0.05 to 1.6 ng/mL final in the wells) of purified tpa standard (as supplied by the manufacturer) were added and allowed to incubate overnight at room temperature. After additional washing, goat antihuman tpa antibody conjugated to peroxidase was added and allowed to incubate for two hours at room temperature. Then the plate was washed again, and ortho-phenylene diamine substrate was added. After 30 minutes in the dark at room temperature, the reaction was stopped by adding 4.5 mol/L H_2SO_4, and the absorbance at 492 nm was read on an eight-channel scanning spectrophotometer (Titertek Multiskan, Flow Laboratories, Irvine, CA). Each euglobulin precipitate was assayed in duplicate at four dilutions in PBS-Tween (fourfold, eightfold, 16-fold, and 32-fold), and the mean value of all dilutions falling on the linear portion of the standard curve was reported. Tpa antigen values in 25 healthy subjects were normally distributed, with a mean of 4.9 plus or minus 2.6 ng/mL (SD) and a range of 0.9 to 11.2 ng/mL. With this assay, quantitative recovery of a wide range of concentrations of purified tpa added to plasma (5 to 50 ng/mL final) was observed, indicating that both free tpa and the tpa/tpa inhibitor complex were detected with equal efficacy.

Measurement of tpa activity. A solid-phase bioimmunoassay similar to that described by Mahmoud and Gaffney[16] was employed to measure tpa activity in euglobulin precipitates of plasma. Microtiter plates were coated overnight with goat antihuman tpa antibody followed by washing and blocking with 2% BSA as described above. Then euglobulin precipitates and a range of concentrations of purified tpa standard (as supplied for the tpa ELISA) were added and incubated for one to two hours at room temperature. After washing, purified human plasminogen (10 μg/mL final) and the plasmin substrate S-2251 (0.15 mmol/L final) in PBS-Tween were added, and color was allowed to develop overnight at 37°C. Absorbance was read at 405 nm on the eight-channel spectrophotometer. Each euglobulin precipitate was assayed in duplicate at three dilutions (twofold, fourfold, and eightfold) and the mean value reported. With this assay tpa activity was not detectable in plasma from most resting normal subjects.

Measurement of tpa inhibitor. The assay of Juhan-Vague et al[17] was used. Tissue plasminogen activator (tpa) purified from Bowes human melanoma cell cultures was added to prewarmed plasma at a final concentration of 50 ng/mL and allowed to incubate for exactly five minutes at 37°C, followed by acidification and recovery of the euglobulin precipitate as described above. The residual tpa activity was measured in microtiter plate wells, as described by Verheijen et al,[14] using cyanogen bromide-fragmented fibrinogen as a stimulant. Since with this method the presence of free tpa activity in the test plasmas could result in a falsely low apparent tpa inhibitor level, each test plasma was also assayed without addition of purified tpa, and the difference in activity between the samples with and without added tpa was used to calculate the tpa inhibitor level. Tissue plasminogen activator (tpa) inhibitor was expressed as ng/mL of added tpa inhibited. Mean tpa inhibitor in 19 normal healthy subjects was 41.9 plus or minus 9.8 ng/mL.

Measurement of a2PI activity. The a2PI activity in plasma was measured spectrofluorometrically using the commercial "Protopath" assay of Dade (Miami), modified according to the method of Matsuda et al[18] to eliminate any effect of alpha-2 macroglobulin on the assay. Briefly, plasma samples were incubated for five minutes at 37°C with Tris-saline buffer pH 7.5 containing 0.2 mol/L methylamine HCl to inhibit alpha-2 macroglobulin, followed by addition of plasmin, further incubation for exactly one minute at 37°C, and measurement of residual plasmin activity spectrofluorometrically. Results of test samples were expressed as a percentage of the activity in pooled normal plasma. The normal range for 15 healthy subjects was 73% to 119% (mean ±2 SD).

Other assays. The DWBCLT was performed as previously described.[12] Briefly, 0.2 mL of freshly drawn blood was pipetted into 1.7 mL of ice-cold acetate-citrate buffer pH 7.4, inverted several times to mix, and kept on melting ice until 0.1 mL of a 50 U/mL thrombin solution could be added. Duplicate samples so processed were incubated at 37°C until lysis occurred. Quick prothrombin times and activated partial thromboplastin times were performed in standard fashion. Levels of fdp/FDP were determined using the Thrombo-Wellcotest (Burroughs-Wellcome, Research Triangle Park, NC).

Statistical methods. Significance of differences in mean laboratory parameters among the patient groups and normal subjects was assessed using the two-tailed Student's *t* test, with a P value of <0.05 considered to be significant. Correlation coefficients were calculated using simple linear regression.

RESULTS

Thirty patients, accrued between January 1983 and June 1986, had sufficient plasma available for performance of all fibrinolytic assays. Twelve patients (group 1) had markedly accelerated fibrinolysis (DWBCLT < two hours). Nine patients (group 2) had moderately accelerated fibrinolysis (DWBCLT between two and four hours). Nine patients (group 3) had normal fibrinolysis (DWBCLT > four hours). Results of standard coagulation assays and liver function tests are displayed in Table 1. Although group 1 patients had a lower mean serum albumin, higher mean total bilirubin, longer mean prothrombin time and PTT, and higher level of fdp/FDPs than groups 2 and 3, the only statistically significant difference among the three groups was observed for the

Table 1. Coagulation and Liver Function Tests (Mean ± SD)

	Group 1	Group 2	Group 3
Serum albumin (g/dL)	2.6 ± 0.5	2.7 ± 0.6	3.0 ± 0.6
Total bilirubin (mg/dL)	8.3 ± 6.4	4.4 ± 2.6	4.1 ± 4.7
Fibrinogen (mg/dL)	119 ± 51	214 ± 43	276 ± 118
Prothrombin time (seconds)	22.7 ± 5.2	18.7 ± 3.3	19.3 ± 5.4
PTT (seconds)	102.8 ± 49.9	74.9 ± 15.1	74.9 ± 41.3
fdp/FDP (μg/mL)	22.0 ± 28.5	17.8 ± 25.7	17.8 ± 16.8
Plasma received (mL)	480 ± 690	344 ± 601	1661 ± 2937

fibrinogen level, which was significantly lower in groups 1 and 2 than in group 3.

Fibrinolytic data are summarized in Table 2. A similarly marked increase in mean tpa antigen was seen in all three groups when compared with the values obtained in normal subjects. Tpa antigen showed no correlation with overall fibrinolytic activity as measured by the DWBCLT ($r = -0.13$, $P > 0.20$). In contrast, tpa activity was significantly correlated with the DWBCLT ($r = -0.45$, $P < 0.05$) and differed markedly among the three groups, being markedly increased in group 1 and essentially undetectable in group 3. The tpa inhibitor also correlated significantly with the DWBCLT ($r = 0.43$, $P < 0.05$) and was significantly lower in group 1 than in group 3. The tpa inhibitor did not correlate significantly with serum albumin ($r = -0.09$, $P > 0.50$) but did correlate significantly with a2PI ($r = 0.47$, $P < 0.05$).

Mean a2PI activity was significantly lower than normal in groups 1 and 2 and was normal in group 3. The a2PI did not correlate significantly with the DWBCLT ($r = 0.35$, $P > 0.05$) or with serum albumin ($r = 0.32$, $P > 0.10$) but did correlate significantly with fibrinogen ($r = 0.59$, $P < 0.01$) and with tpa inhibitor ($r = 0.47$, $P < 0.05$).

Five patients in group 1, three patients in group 2, and five patients in group 3 received blood products prior to measurement of fibrinolytic parameters. The amount of plasma received did not differ significantly among the three groups and did not correlate significantly with any of the fibrinolytic parameters.

DISCUSSION

Tissue plasminogen activator (tpa) is synthesized by endothelium and cleared by the liver. Thus diminished hepatic clearance in cirrhosis would be expected to produce elevated levels of circulating tpa. Using the ELISA technique developed by Bergsdorf et al,[15] we found that marked increases in tpa antigen are common in patients with cirrhosis. Surprisingly, however, the level of tpa antigen did not correlate with overall fibrinolytic activity as measured by the DWBCLT. In contrast, the level of free tpa activity correlated strongly with overall fibrinolytic activity. We interpret this to indicate that in patients with cirrhosis the amount of tpa inhibitor available to bind and neutralize circulating tpa is a critical factor in the development of accelerated fibrinolysis. Those patients whose inhibitory capacity is adequate show no increased fibrinolytic activity, even if tpa antigen is markedly elevated. Patients with insufficient inhibitor exhibit increased fibrinolytic activity proportional to the amount of tpa activity that escapes inhibition. This interpretation is supported by the finding that tpa inhibitor activity was lowest in group 1 and highest in group 3 and correlated significantly with the DWBCLT.

Total tpa antigen in plasma is the sum of free tpa and tpa in complex with its inhibitors.[19-21] In attempting to directly measure the tpa antigen level in whole plasma using the ELISA technique of Bergsdorf et al,[15] however, we found that the apparent level of tpa antigen was not independent of the dilution of plasma assayed, with higher dilutions producing higher apparent tpa antigen levels (data not shown). In contrast, use of euglobulin precipitates resulted in tpa antigen levels that were independent of the dilution of euglobulin fraction assayed. In agreement with other investigators[16] we also found that purified tpa added to plasma was quantitatively recovered in the euglobulin precipitate over a wide range of concentrations. Thus, it is likely that both free tpa and tpa bound to the inhibitor are detected with equal efficacy in the euglobulin fraction using the ELISA of Bergsdorf et al.[15]

There is as yet no agreement on the optimal method for measuring tpa inhibitor activity in plasma. Current assays are not standardized and may have methodologic limitations.[22] The method we have employed, in which a single concentration of purified tpa is added to plasma, has been criticized on the grounds that the amount of tpa inhibitor activity in plasma increases as increasing amounts of tpa are added.[22] Nonetheless, the finding that tpa inhibitor by this assay correlates strongly with both overall fibrinolytic activity and free tpa activity in patients with cirrhosis supports its usefulness in evaluating tpa inhibitory capacity of plasma. This type of tpa inhibitor assay has also proven useful in the

Table 2. Fibrinolytic Assays (Mean ± SD)

	Group 1	Group 2	Group 3	Normal
DWBCLT (minutes)	104 ± 35	176 ± 26	>240	>240
TPA antigen (ng/mL)	29.4 ± 25.9	30.9 ± 20.7	22.1 ± 13.9	5.2 ± 2.6
TPA activity (ng/mL)	7.4 ± 12.1	0.1 ± 0.2	0	0
TPA inhibitor (ng/mL)	16.2 ± 10.5	25.3 ± 15.8	32.0 ± 18.7	41.9 ± 9.8
a2PI (%)	53 ± 22	52 ± 25	77 ± 26	73-119%

study of impaired fibrinolysis in atherosclerotic heart disease.[23]

Tpa inhibitors appear to be synthesized by endothelium, platelets, and placenta.[24-26] Normal plasma may contain both endothelial and nonendothelial tpa inhibitors[27]; the assay method of Juhan-Vague et al[17] measures only the total tpa inhibitory activity in plasma and does not distinguish among the various inhibitors present. Thus, we cannot determine which type of tpa inhibitor is most important in the regulation of fibrinolytic activity in patients with liver cirrhosis. Moreover, since the factors controlling tpa inhibitor synthesis and release are not well defined, it is not yet possible to explain why some patients with cirrhosis are able to counteract increased levels of circulating tpa with increased levels of inhibitor, while others are not. Studies of the extent of protein C activation in cirrhosis may be relevant, since there is evidence that activated protein C inhibits tpa inhibitor release from cultured endothelium.[28] Thrombin may also be an important factor, since subclinical disseminated intravascular coagulation is common in liver cirrhosis,[29,30] and thrombin has been shown to stimulate release of both tpa antigen and inhibitor by cultured endothelium.[31]

We found mean a2PI to be significantly reduced in patients with cirrhosis and accelerated fibrinolysis and normal in patients with cirrhosis and normal fibrinolysis, suggesting a significant contributing role for reduced a2PI in the pathogenesis of accelerated fibrinolysis in cirrhosis. Although a2PI did not correlate with the DWBCLT, the DWBCLT method we used may be insensitive to the inhibitory activity of a2PI, since it involves clotting whole blood in the absence of calcium, thus interfering with the cross-linking of a2PI to fibrin by factor XIII.[32] In contrast to a previous study,[8] we also found no correlation between a2PI and serum albumin, suggesting that factors other than hepatic synthetic rate are important in determining the level of a2PI in cirrhosis.

In addition to increased tpa activity, the possible contribution of increased urokinase-like plasminogen activator activity[7] to the pathogenesis of accelerated fibrinolysis in cirrhosis needs to be considered. Since tpa inhibitors have also been reported to inhibit urokinase,[9,17,24,26] reduced tpa inhibitory activity in cirrhosis may explain the apparently conflicting reports of increased urokinase-like activator activity[7] and normal urokinase antigen[33] in patients with cirrhosis.
